Until the middle of May the water possessed a faint musty odor, after that date in was odorless until December, when it again became musty. The color upon ignition was almost invariably brown; twice in January it was gray.

*Not filtered. ‡ Muddy.

8545

'The water in all cases was odorless. ◆The color upon ignition was brown.

†The abnormal data occasionally found result from the backing of Illinois River water into the Spoon River.

8581 Q. JUDGE SPRINGER: Did you make any investigations as to the waters of the State of Illinois before the passage of the act of the legislature to which reference has been made?

A. Yes, as I have already testified. I began investigations of the water supplies of Illinois in 1889, but did not begin systematic investigation of the Illinois river until the summer of 1894.

Q. What was done then?

A. Then samples were collected at Havana a number of times during the summer of 1894, and in 1895, under the provisions of an appropriation made by the Legislature and assigned by the trustees of the University to the purpose. Analyses of the water supplies of the State were begun and included the examination of samples of water from the Illinois river, and some of its tributaries.

Q. Did you make a preliminary report of those investigations?

A. I did, which report was published by the University in the beginning of 1897, and covered all work done under the provisions heretofore mentioned, up to the end of the year 1896.

Q. Have you that report?

A. I have.

8582 JUDGE SPRINGER: I will offer this report as defendant State of Illinois Exhibit No. 23 for identification.

Said document so marked by the Commissioner.

Q. Professor, did you make any tables of averages based upon the report to which you have just referred?

A. I did.

Q. Have you those tables with you?

A. I have.

Q. Will you produce them?

A. I will. I produce certain tables of averages made from the tables of detailed data just introduced in evidence as Department of Chemistry, University of Illinois A. W. P. Table 1 to 80 inclusive, and State of Illinois Exhibit No. 23 for identification.

Q. Who made those tables of averages?

A. I did.

Q. Based upon the data to which you have referred?

A. Yes.

JUDGE SPRINGER: I offer these tables of averages in evidence and will ask that they be incorporated in evidence as a part of the testimony of this witness, later on.

MR. JEFFRIES: I object to these tables of averages being incorporated into the record as part of the testimony 8583 of this witness or as a part of the testimony in this case for the reasons stated in my objection to the introductions of the tables themselves, and to the State of Illinois Exhibit No. 23 for identification, and I object further for the reason that a table of averages does not correctly represent the conditions of the water in the Illinois river at all times of the year under all conditions and under all circumstances, and that no table of averages such as these appear, can represent the condition, chemically speaking, from a sanitary standpoint of the actual condition of the water of any running stream.

I object for the further reason that the tables of averages conceal certain conditions that are as important for the determination of this case, as those conditions that it reveals, if any it does reveal, and these concealed conditions of the water in a running stream, so far as the experience of the past is concerned, have been the source and the cause of epidemics of water-borne diseases.

JUDGE SPRINGER: I move to strike this out upon the ground that the objection is argumentative and goes to the weight of the testimony and not to its competency or admissibility.

Q. JUDGE SPRINGER: Professor, state whether you have made any charts or plates or diagrams illustrating in a graphic form the data contained in the tables which you 8584 have read in evidence, and also in defendant State of Illinois Exhibit No. 23, for identification?

A. I have.

Q. Will you produce those please?

A. I produce certain charts which are to be known in this investigation as Department of Chemistry, University of Illinois, A. W. P., plates No. V to XLII, inclusive.

JUDGE SPRINGER: I offer these plates in evidence and ask that they be incorporated in the evidence as a part of the testimony of this witness.

MR. JEFFRIES: We object to the introduction of the plates for the same reason stated in our objection to the introduction and incorporation of tables from which they were made, into the record, and which as I understand it, are the tables that were introduced a few moments ago, and known as "Department of Chemistry, University of Illinois, A. W. P., Table 1 to 80 inclusive."

THE WITNESS: The plates are numbered V to XLV inclusive, and from V to XVII both inclusive are as follows:

8598 Adjourned until 10:00 A. M. following day, Friday, October 16th, 1903.

8599 10:00 A. M., Friday, October 16, 1903. Continuation pursuant to adjournment. Present, the Commissioner and same counsel representing the respective parties.

PROF. ARTHUR W. PALMER,

resumed the stand for further direct-examination by Judge Springer, and testified as follows:

Q. Professor Palmer, please state who assisted you in making the tables of analyses that you have read in evidence since you have been testifying in this case?

A. Mr. C. V. Millar, up to the summer of 1900, now of Joplin, Missouri, and Mr. R. W. Stark, right through the entire series.

Q. Who is Mr. Millar?

A. Mr. Millar is a chemist who assisted me in doing the work of investigation of the waters, and did a great deal of the routine analytical work that is incorporated in these tables that are in evidence.

Q. What part did Mr. Stark perform?

A. Mr. Stark also had charge of a portion of the work and
after Mr. Millar's resignation had chief control of the
8600 work under me. Both of these men were responsible to
me throughout, for the work. The work was all done
under my immediate supervision.

Q. And state whether their ascertainments were submitted to you from time to time?

A. From day to day the results were brought to me and were incorporated into these tables which are in evidence.

Q. Were any other persons than those you have mentioned. engaged in making the chemical analyses?

A. Several other persons helped with portions of the work but they were responsible to me directly and to Mr. Stark and Mr. Millar, who under me supervised some of the minor details of the work.

Q. Were the tables so far as you know, and the ascertainments contained in them made by you three jointly so that you three can determine whether they are accurately made?

A. They were.

(Witness Prof. Palmer temporarily withdrawn from the stand.)

8601 R. W. STARK,

called as a witness in behalf of the defendants, being first duly sworn by the Commissioner, was examined in chief by Judge Springer and testified as follows:

Q. State your name, residence and occupation?

A. My name is R. W. Stark, Champaign, Illinois; I am a chemist employed in the State Water Survey.

Q. Where were you educated Mr. Stark?

A. At the University of Illinois.

Q. What courses did you take there?

A. I took the chemical course.

Q. How long were you engaged in that study?

A. I pursued the chemical course for four years, and was graduated in 1895.

Q. Did you attend any other college than this?

A. I have not.

Q. Did you receive any degree?

A. I received the degree of B. S.—Batchelor of Science.

Q. What has been your occupation since that time, since 1895?

A. For two years I did various things; one year was passed upon a farm. In 1897 I was employed upon the Water Survey of Illinois.

8602 Q. What was the nature of your duties in connection with the Water Survey of Illinois?

A. For the first three years I was making chiefly mineral analyses and some clerical work. After Mr. Millar's resignation I was made chief assistant.

Q. Of what?

A. Of the State Water Survey, and I then had charge of the sanitary chemical analyses in the laboratory work.

Q. Have you had any experience, and if so, how much, in making chemical analyses of water?

A. Since June 18th, 1900, I have been employed constantly in making sanitary chemical analyses.

Q. What instructions if any did you have in that line of work and what experience; what was your experience or practice as a chemist?

A. Prior to my employment?

Q. Yes?

A. We have a course, or had a course in the University on sanitary chemical analysis, and I took this course in the University.

Q. Did that embrace the making of chemical analyses of water?

A. It did.

8603 Q. My questions in this case are directed solely to the matter of your knowledge in the making of chemical analyses of water?

A. Yes.

Q. It was that that I desired to call out. Then state what your experience has been in making chemical analyses of water. How long have you made such analyses, and about how many such analyses have you made?

A. About how many of such?

Q. Yes?

A. I have made about between 6,000 and 7,000 I should judge.

Q. State whether you assisted Professor Palmer in making the chemical analyses which he prepared, together with you and Mr. Millar during the years 1897 to 1902?

A. I did.

Q. You heard Professor Palmer's statement a few minutes ago did you?

A. I did.

Q. And you were the person referred to by him as having assisted in making those analyses?

A. I am.

Q. State whether the analyses about which he testified, and in which you participated were entered upon any tables as a matter of record?

8604 A. They were.

Q. Who entered those?

A. Mr. Millar and myself had charge of them; that is the different memoranda as made at the time.

Q. Did Professor Palmer make any of those?

A. Not the sanitary—we made the memoranda.

Q. Of course you don't know all that Professor Palmer has done himself?

A. Oh, no.

Q. You only know what you did?

A. Yes.

Q. State whether the results recorded by you in connection with these analyses were correctly stated in the tables which were prepared by Professor Palmer and yourself and Mr. Millar?

A. So far as I am able to konw, they were.

Q. And so far as you yourself performed the work?

A. They were.

Q. As to that you know that those were correct?

A. Yes sir.

Q. I call your attention to table No. 1, down to and including table No. 80, put in evidence by Professor Palmer; were those the tables that you assisted in making?

A. They were.

8605 Q. I now call your attention to tables made by him, as a part of the sanitary survey of Illinois covering periods from 1897 to the end of 1902, known as Department of Chemistry, University of Illinois, A. W. P. 1 to 80. Do you recognize those tables?

A. I do.

Q. Are those the ones that you participated in making?

A. I did.

Q. And so far as the entires were made by you, they are correct ascertainments of the analyses made by you at the time?

A. They are.

DIRECT-EXAMINATION,

By Mr. Todd.

Q. Now Mr. Stark, you worked under the direction and supervision of Professor Palmer in the laboratory analyses in the University of Illinois, of these water samples as received there, did you not?

A. I did.

Q. And your work was done under his direction and supervision?

A. It was.

8606 Q. You merely worked as an assistant to Professor Palmer in doing this work?

A. Yes sir.

CROSS-EXAMINATION,

By Mr. Jeffries.

Q. When you spoke of making sanitary chemical analyses do you mean that you made those from a sanitary standpoint, and as a sanitarian, taking into consideration the source of pollution, extent of pollution, and everything of that kind, or were they made simply with reference to the chemical constituents contained in the samples of water which you analyzed?

A. They were made so far as I was concerned, simply taking into consideration the various chemical constituents.

8607 PROF. ARTHUR W. PALMER,

resumed the stand for further direct-examination by Judge Springer, and testified as follows:

Q. Professor, I now call your attention to the tables of chemical analyses read in evidence by you yesterday, beginning with table "Department of Chemistry, University of Illinois, A. W. P. No. 1." Please explain briefly the nature of the entries upon this, and what the table is intended to illustrate?

MR. JEFFRIES: Now I object to any explanation being made by this witness with reference to what these tables show, for the same reasons stated in my objection to the introduction of the tables themselves.

A. Table marked "Department of Chemistry, University of Illinois A. W. P. 1" shows the results of analyses of samples of water from Lake Michigan at Chicago, drawn from the tap at No. 465 State Street; that is in the building of the college of Pharmacy of the University of Illinois, the water at that point coming from the Four-Mile intake, opposite Fourteenth Street.

8608 The data in this table include the analyses of samples collected regularly every week for the year 1897, reaching from the 4th of January 1897, to the 27th of December of that year. The data which are set forth in this table include all of the usual determinations of various constituents as determined in chemical analyses of waters for sanitary purposes.

The first column at the left hand of the table gives the serial number which was placed upon the sample of water; that is, upon the certificate of the collector, and upon the bottle containing the sample, at the time it was received at the laboratory, by which number the sample of water was identified throughout the analysis, and the tabulations and all discussion which follows:

In the second column there is given the date of collection.

In the third column the date of examination, which examination began immediately upon receipt of the sample at the laboratory.

In the third column, the determination of turbidity is noted.

In the fourth column the sediment.

In the fifth column the color.

In the sixth column the odor.

In the seventh column the total residue on evaporation
560 of a portion of the original sample.

In the eighth column the total residue on evaporation of the filtered portion of the sample.

In the ninth column the suspended matters as determined by the differences between the figures in columns 8 and 7.

In the tenth column the total loss on ignition, that is the loss upon igniting the residue from evaporation of the unfiltered sample.

The eleventh column the loss on ignition of the total residue on evaporation of the filtered water, which appears in the column marked "Dissolved" and numbered 8.

In the twelfth column there are recorded the results of the determination of chlorine.

In the thirteenth the total oxygen consumed.

In the fourteenth the oxygen consumed by organic matters in the filtered portion of the sample.

In the fifteenth column the oxygen consumed by matters in suspension as determined indirectly by the difference between the two next preceding columns.

The sixteenth column contains the figures representing the proportions of nitrogen as free ammonia.

The seventeenth column the nitrogen as albuminoid ammonia,—the total, that is the proportions obtained by the
8610 analysis of an unfiltered portion of the sample.

The eighteenth column contains figures showing the proportions of nitrogen as albuminoid ammonia, derived from the matters held in solution in the water, as determined upon the filtered sample.

The nineteenth column contains figures representing the proportions of nitrogen as albuminoid ammonia derived from matters in susupension and constituting the difference between the figures in columns 18 and 17.

Column 20 contains the figures representing the proportions of total organic nitrogen as determined by the Kjel Dahl process upon the original unfiltered sample.

Column 21, similar determination upon the sample after filtration.

Column 22 the total organic nitrogen derived from matters suspended in the water, and determined by the difference between the figures in columns 20 and 21.

Column 23 shows the figures representing the proportions of nitrogen as nitrites.

Column 24 the proportions of nitrogen as nitrates.

Q. State whether the other tables following in this series contain similar data only differing as to the place from which the water was taken?

8611 A. This table is a typical number of the entire series, and represents the same sort of data in all respects as these appearing upon the other tables included in this series.

Q. Except as to the place where the water was taken?

A. Except as to the source of the sample of water, which, for each given point is noted upon the table in question.

The table also shows upon its lower lines the averages for the first six months, for the second six months, and for the entire year.

Q. The averages of what?

A. Of the analyses above.

Q. You may state what those averages were on this table?

A. What they were?

Q. Yes, the averages recorded there?

A. Well, do you want me to read the averages?

Q. Yes?

A. For this particular table the averages at the bottom show simply the general averages for the entire year, for the reason that variations in the water of Lake Michigan are so slight in the different seasons that there seemed to be no particular object in making averages for lesser periods than the entire year. Most of the other tables referring to the
8612 other points have the three sets of averages above referred to, namely those for the first six months, the second six months and the entire year.

Q. Proceed now and state what the averages were on these ascertainments?

A. We made no attempt to give averages for turbidity and sediment, since these were indicated merely by the terms as herein before testified to,—"Much," "Distinct," "Considerable," "Decided" and so on, which do not readily lend themselves to the preparation of averages. The color too, was not averaged, although expressed in figures in the table. The first averages recorded are those for the residue on evaporation. The average for this particular table representing the total residue upon evaporation is 151.7 parts per million.

The average for the total residue on evaporation of the filtered sample, representing matters in solution was 136.6 parts per million.

The average for the suspended matters, 15 parts per million.

The average loss on ignition, total, 11.9 parts per million.

The average loss on ignition of dissolved substances 9.6 parts per million.

8613 The average for the chlorine 2.9 parts per million.

The average for the total oxygen consumed, 3.3 parts per million.

The average for the oxygen consumed by dissolved substances, 2.7 parts per million.

I note here that the average for the oxygen consumed by suspended matters has not been printed in this table. I will supply it however; it is a mere matter of simple calculation.

The average for the nitrogen as free ammonia is .005 parts per million.

The average for the nitrogen as total albuminoid ammonia was .102 parts per million.

For the nitrogen as albuminoid ammonia yielded by matters in solution .076 parts per million.

The nitrogen as albuminoid ammonia derived from suspended matters, .036 parts per million.

The average for the total organic nitrogen by Kjel Dahl process, .268 parts per million.

For total organic nitrogen, yielded by dissolved substances, .195 parts per million.

For the total organic nitrogen yielded by matters in suspension .73 parts per million.—This is an error, it should be .073,—a typographical error in the plate which I will
8614 verify and get into the record latter.

The nitrogen as nitrites, and it will be observed that in the column for which this average is made, nitrites are frequently recorded as being absent, as indicated by the word "none", in this column, the average was .005 parts per million.

The average of the column giving the data for nitrates is .2 parts per million.

Q. These averages are for what year?

A. For the year 1897. Lake Michigan water at Chicago as described above.

Q. Coming from the Four-Mile crib?

A. Coming from the Four-Mile Crib, opposite Fourteenth Street and drawn at a tap in the College of Pharmacy of the University of Illinois, at 465 State Street.

Q. State whether you have a similar table of Lake Michigan water for the year 1898?

A. I have here before me a similar table, the analyses of Lake Michigan water at Chicago, drawn from the same source, which has just been described, but for the year 1898, which table is designated as No. 2 in the series.

Q. Does that table contain the averages at the bottom of the sheet?

8615 A. It does.

Q. State whether you have a table containing similar data based upon the waters from Lake Michigan at the point you have indicated for the year 1899?

A. I have. It is indicated as No. 3 of this series.

Q. And have you another table of data in reference to analyses of Lake Michigan water from the point you have indicated for the year 1900?

A. I have. It is No. 4 of this series.

Q. Does that table contain also a statement of averages for the year, as table No. 1 did?

A. It does.

Q. Now did you have any ascertainment of dissolved oxygen?

A. Not for the entire series of four tables, as I remember it, but for a portion of them.

Q. State what portion of the time covered by these tables was it during which you obtained results as to dissolved oxygen?

A. The dissolved oxygen determination covered a portion of the year 1897, the entire years, 1898 and 1899, and a portion of the year 1900.

Q. Have you put the plates in evidence heretofore which illustrate the dissolved oxygen to which you have referred? 8616

A. I have.

Q. Where did you obtain the data upon which these determinations were made?

A. The data were obtained by the analyses of samples especially collected for the making of dissolved oxygen determinations, which samples were taken at the same time and at the same place as the samples which were subjected to chemical analyses and the date from which are recorded on tables I to IV of this series, put in evidence yesterday, and just referred to.

JUDGE SPRINGER: Let this data be marked as defendant State of Illinois' Exhibit No. 24 for identification. These are the data which are represented in the curves of the plates already put in evidence, and further explanation of which will be made hereafter. These plates are known as "Department of Chemistry, University of Illinois Plates V to XLV, inclusive."

Q. I will ask the witness to explain the curves in plate V to which reference has just been made, showing these proportions of dissolved oxygen.

MR. JEFFRIES: I object to any explanation of the witness with reference to the curves on Plate V, for the reasons stated in my objection to the introduction of the plate in evidence.

A. An explanation of the meaning of the different lines
8617 upon the plate appears at the top of the plate, and further
I may say that one line represents the temperatures of the water samples as they were collected at the tap. This line being toward the bottom of the plate, or the section of the plate, referring to the year. The next line from the bottom represents the proportion of oxygen contained in the sample in milligrams, of oxygen per liter of water.

The third curve which is at the top of the series in each section represents the percentage of saturation. It will be observed of course that the quantity of oxygen contained in the water varies practically inversely, as the temperature. At lower temperatures the water holds a greater quantity of oxygen in solution; at higher temperatures it holds less. The curve representing the saturation figure, however, varies in a manner which is not precisely similar to the variations of temperature and of content of oxygen in quantity for the reason that the water is at times more than saturated. That is, holds in solution a greater quantity of oxygen than can be held in a state of stable equilibrium at that temperature and which doubtless is slowly diffusing from the water into the air. At other times the percentage of saturation falls below the 100 point, that is
the water is not fully saturated with dissolved oxygen.
8618 Inspection of the lines will show the facts revealed by
the figures in the table, which is offered as an exhibit under State of Illinois Exhibit No. 24 for identification, and it is apparent that in general during the first six months of the year the water is fully saturated or even supersaturated, while during the latter part of the year, particularly in the years 1897 and 1899, the proportion of saturation was less than 100; not at all times, but during most of the time; during the year 1898 the variations from the saturation point are not so marked nor so frequent.

Q. I now call your attention, professor to table 5 of this series which is table "Department of Chemistry, University of Illinois, A. W. P. V." Please state generally what this table is intended to illustrate and what is the character of the data which it contains?

MR. JEFFRIES: I object to any explanation on the part of the witness or any testimony being given by the witness in reference to this table, or with reference to what it shows, for the same reasons stated in my objection to the reading of the tables into the record.

A. Table 5 of this series represents the numerical data of the analyses of waters from the Illinois and Michigan canal at Lockport for the year 1897.

8619 Q. Please state briefly what this table represents?

A. It represents the series of analyses of water from the Illinois and Michigan Canal at Lockport for the year 1897, the different determinations being precisely the same as those heretofore described with respect to table No. 1 of this series, and includes at the bottom, averages not only for the entire year, but for the first six months and the second six months as well.

Q. Will you please state those averages for the first six months?

A. The averages for the first six months covering regular weekly collections from January 4th to June 29th inclusive, are as follows:

Total residue on evaporation,	684.1	parts per million,
Dissolved,	518.	do.
Suspended,	136.	do.
Loss on ignition—total	84.2	do.
Dissolved,	53.1	do.
Chlorine,	121.7	do.
Total oxygen consumed,	42.1	do.
Dissolved—that is, oxygen consumed by dissolved matters,	18.4	do.
Oxygen consumed by suspended matters,	23.7	do.
Nitrogen as free ammonia,	10.6	do.
8620 Total albuminoid ammonia,	3.2	do-
Nitrogen as albuminoid am-		

monia derived from dissolved substances,	1.31	do.
By suspended matters,	1.93	do.
Total organic nitrogen,	5.79	do.
Total organic nitrogen derived from matters in solution,	2.12	do.
By matters in suspension,	3.66	do.
Nitrogen as nitrites,	.06	do.
Nitrogen as nitrates,	.401	do.

8621 Q. Now the next six months please?

A. For the second six months covering the samples collected on the dates indicated in the table ranging from July 5th to December 28th, 1897.

Total residue on evaporation,	495.7	parts per million,
Dissolved,	438.2	do.
Suspended,	57.5	do.
Lost on ignition,	53.6	do.
By dissolved substances,	34.1	do.
Chlorine,	108.8	do.
Oxygen consumed,—total,	34.3	do.
By dissolved matters,	18.6	do.
By suspended matters,	15.7	do.
Nitrogen as free ammonia,	14.3	do.
Total albuminoid ammonia,	2.2	do.
From dissolved substances,	1.38	do.
From suspended matters,	.8	do.
Total organic nitrogen,	4.05	do.
By dissolved matters,	2.51	do.
From suspended matters,	1.54	do.
Nitrogen as nitrites,	.018	do.
Nitrogen as nitrates,	.273	do.

8622 Average for the entire year, that is from January 4th, to December the 28th, inclusive:

Total residue on evaporation,	591.8	parts per million,
Dissolved,	494.2	do.
Suspended,	97.5	do.
Loss on ignition, total,	69.42	do.
By dissolved,	43.8	do.
Chlorine,	115.4	do.
Total oxygen consumed,	38.3	do.

Dissolved,	18.1	do.
Suspended,	20.2	do.
Nitrogen as free ammonia,	12.4	do.
Total albuminoid ammonia,	2.72	do.
From dissolved matters,	1.34	do.
From suspended matters,	1.38	do.
Total organic nitrogen,	4.94	do.
From dissolved matters,	2.31	do.
From suspended matters,	2.62	do.
Nitrogen as nitrites,	.039	do.
Nitrogen as nitrates,	.339	do.

Q. Now for the entire year?

A. That is for the entire year. At the bottom of the table there is a line indicating the general character of the odor
8623 during the year. The statement is that this water always had a decided odor described as musty or gassy, and further the line with color upon ignition is always brown. Similar statements to these are made at the bottom of the various other tables in this series.

Q. I call your attention now to table 6 of this series. Please make a brief statement of the data contained in this table.

MR. JEFFRIES: I object to any statement being made by this witness or any facts being drawn by him from it, for the same reason stated in my objection to the reading of the table into the record.

A. In table No. 6, we have the data for the water of the Illinois and Michigan canal at Lockport similar to the one just described, but for the year 1898.

Q. State whether the averages are computed at the bottom of this table as in other cases?

A. The averages for the first six months the second six months and the entire year have been computed and are recorded at the bottom of the table as in the preceding case.

Q. I now call your attention to table 7 of this series and ask you to explain the character of the data contained in this
8624 table?

MR. JEFFRIES: I desire to make the same objection to table 7 as was made to table 6.

A. Table 7 is precisely similar in all respects to table No. 6, but covers the year 1899.

Q. At what place?

A. At the Illinois and Michigan Canal at Lockport.

Q. Are the averages stated in that table also?

A. They are.

Q. For each six months and the for the whole year?

A. That was covered in my statement "Precisely similar in all respects."

Q. I now call your attention to table 8 of this series and ask you to explain the character of the data contained in that table?

A. Table No. 8 is precisely similar in all respects to tables 5, 6 and 7, but for the year 1900, and table 9 is likewise similar in all respects to Nos. 5, 6, 7 and 8, except that it covers the year 1901 and during a portion of that year the samples were collected monthly instead of weekly as in the other tables in this series.

Q. All taken at what place?

A. All being analyses of the water of the Illinois and 8625 Michigan canal, collected from this canal at Lockport.

Q. Now I call your attention to tables 10 and 11 of this series and ask you to state the character of the data which are embraced in these tables?

A. Tables Nos. 10 and 11, being the data of analyses of samples of water collected from the sanitary canal or Chicago main drainage channel at Bear Trap Dam at Lockport and for the years 1900 and 1901. The collections for some portions of the year being made more frequently than once a week and during a portion of the year 1901 being made once a month.

Q. Now I call your attention to tables 12, 13 and 14 of this series and ask you to explain the character of the data contained in these tables.

A. Tables 12, 13 and 14 of this series contain the results of analyses of samples of water collected from the Desplaines river at Lockport. The samples having been taken beside the old stone bridge which crossed the river at this point before the changes made in the bed of the stream at the time the sanitary canal was finished at this point, or just thereafter.

Q. Did these samples come from the Desplaines river before that river had received any of the discharges from the Sanitary Canal?

A. They did.

8626 Q. I now call your attention to tables 15 and 16 of this series and ask you to explain the data contained in these tables?

A. Tables Nos. 15 and 16 of this series represent the figures obtained from the analyses of the water of the Desplaines river at Joliet, the samples having been taken just above Dam No. 1 in the town of Joliet. These tables are supplementary to the tables and data which have hertofore been placed in evidence in part of the report made by me of analyses made in behalf of the sanitary district of Chicago, and included in the series of tables 1 to 80 heretofore placed in evidence and discussed.

Q. What are the periods covered by these?

A. The period covered by tables 15 and 16 of this series is the year 1901, one table giving the data from the analyses of samples taken at the east side or south side of the stream at the point above indicated, and the other table, No. 16, giving the data of the analyses of samples collected at the west or north side of the stream at this point.

Q. What was the object of taking the samples at the place you have indicated?

A. Observation of the waters at this point flowing through the bed of the Desplaines river and variations in the an-
8627 alyses of samples collected at mid-channel at this point
in the previous year led us to take these two sets of samples, one toward one bank and the other toward the other bank of the stream at Joliet, in order to secure the data respecting the different compositions of the water of the two sides of the stream, and with reference to a study of the mixing of the waters of the upper Desplaines river, of the Sanitary canal and of the Illinois and Michigan canal after they had come together at Lockport, four miles above, and at the point a few hundred yards above that of collection at Joliet.

Q. State whether the points you have indicated were above or below the outlets of the sewers of Joliet?

A. This point was above that at which the sewers of Joliet discharged into the stream, although a portion of the sewage of Joliet and the manufacturing industries, and from the State Penitentiary enters the Illinois and Michigan Canal a short distance above this point, about three miles below the point at which collections were made at Lockport, and above the point where the Illinois and Michigan canal joins with and crosses the Desplaines river; that is a portion of Joliet sewage and manufacturing waste just referred to, mixes with these various bodies of water, occupying the bed of the Desplaines river.

8628 Q. Does this table also contain general averages based upon the two samples or upon the samples separately?

A. The averages at the bottom of these two tables are the averages of the data included in each table respectively.

Q. Did you note any marked difference in the two places in the river and if so you may state where those differences appear?

A. There is a very considerable difference between the averages obtained from the analyses of samples collected at one side of the stream at this point, and the averages obtained from the analyses of the samples collected at the other side, these differences being due to the incomplete mixing of the several bodies of water which are passing down the valley of the Desplaines at this point, or perhaps I had better say the bed of the Desplaines river at this point. The variations being caused at this time by variations in the discharge at the Bear Trap Dam, by variations in the quantities of sewage pumped from the south fork of the Chicago river into the Illinois and Michigan canal and variations in the flow of the upper Desplaines river.

Q. Do these tables embrace the entire year 1901?

A. These data cover the entire year 1901, but in the early part of the year monthly samples only were taken. while
8629 in the latter part of the year samples were collected once a week. I may expain here that in cases of tables of analyses which were not taken uniformly once a week throughout the year, monthly averages were first made, and the years averages made from these for the purpose of securing a greater uniformity in the averages and obtaining figures which were more truly representative of the average condition of the water throughout the year.

Q. I now call your attention to tables 17, 18, 19 and 20 of these series and ask you to explain the data contained in these tables?

A. Tables Nos. 17, 18, 19 and 20 of this series, give the results of analyses of water taken from the Illinois river at Morris, between nine and ten miles below the confluence of the Desplaines and the canal, which by their union form the Illinois river, the tables covering the years 1897, 1898, 1899 and 1900 respectively. The collections were made regularly each week throughout the respective years from the beginning of January to the end of December. In most of the years the entire series of determinations referred to in my description of table No. 1 of this series is made, but in the earlier years, namely, 1897 and 1898 the determinations of albuminoid ammonia and oxygen consumed, and of total organic nitrogen were not
8630 made for matters in solution, only the totals for the original unfiltered water samples being made in this year. For the other years, namely, 1899 and 1900, the entire series of determinations upon both the original sample and the filtered portion were made. At the bottom of each of these tables there appear averages for the first six months, the second six months and the entire year, as in the case of the tables previously described.

ADJOURNED until 2:00 P. M., same day.

2:00 P. M., Friday, October 16, 1903.

8631 Continuation pursuant to adjournment.

Present, the Commissioner and same counsel representing the respective parties.

C. V. MILLAR,

called as a witness in behalf of the defendants, being first duly sworn by the Comissioner, was examined in chief by Judge Springer and testified as follows:

Q. State your name, residence and occupation?

A. C. V. Millar; I reside in Joplin, Missouri; my occupation is that of assayer or chemist.

Q. Where were you educated Mr. Millar?

A. Well I received the common country school education at Mattoon, Illinois; from there I went to the University in the fall of 1889.

Q. Which university?

A. University of Illinois, in the fall of 1889, and went through the four years' course and graduated in 1893, and in 1893 and 1894 I held a fellowship and graduated from the post-graduate course in 1894.

8632 Q. What degrees did you take in the college?

A. In 1893 I received my batchelor's degree, and in 1894 I received my Master's degree besides.

Q. What branches were you studying in the University of Illinois principally?

A. I took the special course of chemistry.

Q. After you finished your courses in college did you pursue any chemical studies or prosecute any chemical work in reference to making analyses of water?

A. Well after I graduated in 1894, I came back in September of 1895, and I was employed by the Water Survey Department.

Q. Of the University of Illinois?

A. University of Illinois, yes.

Q. How long did that employment continue?

A. I remained in that employment until the 15th day of June, 1900.

Q. What have you been engaged in since that time?

A. I went to Joplin, Missouri, where I reside now, and ever since have been engaged in the assay business.

Q. About how many analyses of water have you made during the time you were in college and since that time?

A. Well, when I was in college I only made a few in my senior year, but I studied a branch of chemistry, and in

8633 the Water Survey Department it was between 7,000 and 8,000, as close as I can remember it.

Q. Between 1895 and the year 1900, did you make any chemical analyses of water in connection with Professor Palmer of the University of Illinois?

A. Yes.

Q. What part did you perform in reference to those analyses?

A. I did the chemical analysis of the water.

Q. That is, of a part of it?

A. Yes sir.

Q. Who received the samples and made records of their receipt and what time they were analyzed?

A. I received them.

Q. Did you enter the dates of all the certificates accompanying these samples on the tables containing your chemical analyses?

A. Yes sir. We always dated them when we received them.

Q. And the data in reference to the time it was received,—from what source did you get them—I mean the data as to when the collection was taken?

A. We got that from the men that shipped the samples to us.

Q. Did that appear upon the certificate?

A. Yes sir.

8634 Q. And you entered all those dates correctly from the certificates and the correct date as to the time of making the analysis?

A. Yes sir.

Q. And so far as entered by you they are correct?

A. Yes sir, so far as I know.

Q. In reference to the results of the chemical analyses of the waters during that time, that were analyzed in the University of Illinois, state whether the chemical analyses made by you are correctly reported in the tables that were made at that time?

A. They were.

Q. Would you recognize those tables if you were to see them?

A. Yes sir.

Q. I call the witness' attention to tables 1 to 80 inclusive, in this series—

MR. JEFFRIES: I object to the witness referring to the publication now before him, because it does not constitute, and are not the tables that were made by this witness.

JUDGE SPRINGER: Do you mean that you object to using this book? They are the same ones read into the record. Do you object to the using of the forms that are in this book?

MR. JEFFRIES: I object to this witness referring to 8635 that book because Professor Palmer stated that those tables were made up by himself: In other words, I understood from him that the proof was read by him, and the accuracy and correctness of the tables—now I object to this witness referring to those tables in answer to the question which you have propounded to him.

JUDGE SPRINGER: Let me change my question a little then.

MR. JEFFRIES: My objection goes to this extent; that the witness has no right to speak or to examine the tables from the book or the printed tables which have been incorporated into the evidence in this case, because this witness had nothing to do with their preparation.

JUDGE SPRINGER: My question relates solely to the tables 1 to 80, put in evidence by Professor Palmer, and these are the tables to which I have called the attention of the witness.

MR. JEFFRIES: And which refer to chemical analyses made by Professor Palmer during certain dates.

JUDGE SPRINGER: Which tables refer to chemical analyses of which Professor Palmer has testified, and to the fact that those tables were made by him with the assistance of this witness and of Mr. Stark who testified this morning, and that the three were engaged in making different parts of these analyses, and making these entries.

MR. JEFFRIES: Well Judge you have not connected the
8636 witness with the time he was employed at this work.

JUDGE SPRINGER: Yes I have, 1895 to 1900.

MR. JEFFRIES: Yes, but you haven't connected the tables with the time the witness made these analyses, and therefore my objection is still good.

Q. JUDGE SPRINGER: Will you state the time now that you were engaged, again?

A. From September, 1895 to the 15th of June, 1900.

Q. The tables now before you which were read in evidence by Professor Palmer were made from waters taken during the years 1899 and 1900. During that time were you engaged with Professor Palmer in making chemical analyses of water?

A. Up until June 15th of 1900.

Q. Until June 15th, 1900?

A. Yes sir.

Q. From that time as appears by these tables, you are not cognizant of what was done?

A. No sir.

Q. State whether the chemical results of the analyses made by you were correctly recorded upon those tables during the time mentioned, namely, for the year 1899, and the year 1900 up to June 15th?

A. I recorded them on these blanks correctly, which were
8637 given to me.

Q. Then so far as the part that you performed is concerned, you made the correct entries according to the results of the chemical analyses?

A. Yes sir.

Q. Prior to the year 1899 were you engaged in assisting Professor Palmer in making chemical analyses of water?

A. From 1895 to 1899 I was.

Q. During that time did you participate in the way of assistance to Professor Palmer and under his direction, in making analyses of the waters that came to the University from points taken on the rivers mentioned in the tables to which I have just called your attention?

A. Yes sir.

Q. And from other points that were involved in the tables that were made during the years 1895 to and including 1898?

A. Yes sir, I was connected with him.

Q. Did you make in those tables that were prepared at that time, correct entries of the analyses of waters made by you?

A. Yes sir.

8638 CROSS-EXAMINATION,

By Mr. Jeffries.

Q. These analyses that you made, as I understand it, were made under the supervision of Professor Palmer?

A. Yes sir.

Q. And all that you did was simply to ascertain as best you could the chemical constituents of the samples of water that were placed in your hands for analyses?

A. We had certain determinations which we made on each water, and that was what I did.

Q. Did you determine all of the chemical constituents of the water?

A. No sir.

Q. You made certain chemical determinations of the water that was placed in your hands?

A. Yes sir.

Q. Without reference to the manner in which they came into your hands except through Professor Palmer?

A. What was that question again?

Q. Without reference to how they came into your hands. In other words, without reference to the source of the water or anything of that kind?

8639 A. Yes sir.

Q. You simply made the chemical analyses in the laboratory and recorded them on the sheets

A. Yes sir.

Q. Who else assisted you besides Mr. Stark?

A. There was one gentleman by the name of Edwards that assisted me part of the time and one by the name of Mr. Manhard, and a man by the name of Mr. Koch, and I think that is all. I haven't thought about it.

RE-DIRECT-EXAMINATION,

By Judge Springer.

Q. You knew however, that the work that was done by them in assisting you was correctly entered, do you, in these tables?

A. Yes sir, I entered the work.

RE-CROSS-EXAMINATION,

By Mr. Jeffries.

Q. You don't know though that their chemical results were properly ascertained, as done by these other parties?

A. I have reason to believe they were. They were under my direction.

8640 Q. Being under your direction you don't know of your own knowledge, that they were?

A. No sir.

BY JUDGE SPRINGER:

Q. Were they done in your presence?

A. Yes sir.

By agreement of counsel the signatures of the witness Stark and witness Millar to their evidence, are hereby waived.

Counsel for the complainant and defendants agree that the testimony of witnesses hereafter to be examined need not be signed by them unless the witness desires to do so, or the Commissioner desires to have them, or unless either of the parties shall desire the signature of any particular witness, in which event it shall be made known at the time the witness testifies, and in all cases where witnesses do not sign their testimony the typographical corrections shall be made,, if any are necessary, by the Commissioner and he shall thereupon certify to the evidence as taken.

8641 PROF. ARTHUR W. PALMER,

resumed the stand for further direct-examination by Judge Springer, and testified as follows:

Q. Professor, I now call your attention to tables numbered 21, 22 and 23 of this series, and ask you to state what is the character of the data contained in these tables?

A. The data upon tables 21, 22 and 23, are the results of analyses of the waters of the Illinois river at Ottawa, collected at a point just above the mouth of the Fox River, and covering portions of the years 1899 and 1900, and 1901.

Q. Please state what portions of the years mentioned are covered?

A. For 1899 the series of analyses run from the 19th of June to the 28th of December.

For the year 1900 they extend from the 4th of January to the 6th of October.

And for the year 1901 they extend from July 20 to October 29.

Q. Were they taken at one point in the river or at cross-sections?

A. They were taken at one point.

8642 Q. Where was that point?

A. That point was about a mile north or east of the mouth of the Fox river.

Q. Was it above the point of the outlets of the sewers of Ottawa?

A. It was.

Q. State whether at this point there had been accomplished a mixing of the waters coming from the Desplaines, the Kankakee the Sanitary canal and the Illinois and Michigan Canal?

A. At this point the mixing of the waters of the Kankakee with the waters of the Desplaines, which latter include the discharges from the old or the Illinois and Michigan canal, the sanitary canal, and the waters from the upper Desplaines, is not complete, and this accounts for certain variations in the analytical data. Certain cross section determinations show that this mixing at Ottawa is not complete.

Q. Is this point below or above the outlet of the old Illinois and Michigan canal?

A. It is about eighteen miles above the outlet of the old Illinois and Michigan canal, but at Ottawa and at various other points along the course of the canal there are discharges of water from the canal into the Illinois river.

Q. Do the tables just mentioned contain the averages
8643 of the analyses?

A. They do.

Q. As in the other cases?

A. Yes.

Q. This will appear on the bottom of each page, I presume?

A. Yes sir.

Q. I now call your attention to tables 24, 25, 26 and 27 of this series and ask you to explain the data which are recorded in these tables?

A. The data upon the tables 24, 25, 26 and 27, are the result of analyses of samples of water collected from the Illinois river at LaSalle, during the years 1897, 1898, 1899 and 1900 respectively.

Q. During what portions of the respective years do the tables cover?

A. For the year 1897, the collections cover the period from January 5th to December 29th inclusive, regular collections once a week.

For the year 1898 the collections cover the period January

4th to December 19th, inclusive, but the collections were not made weekly throughout. There were some difficulties about getting the collections made and in some months, as for instance, March, there is but one collection in the month, but the series extend with the breaks I have mentioned, through-
8644 out the year.

For the year 1899, the collections extend from February 15 to December 26.

For the year 1900, they extend from January 2nd to October 2nd.

Q. Are the averages entered upon each of these sheets at the bottom of the page?

A. Upon each of these tables the averages for the first six months, and the second six months and for the entire year, appear at the bottom.

Q. I now call your attention to tables 28 to 32 inclusive, and ask you to explain the character of the data contained in these tables?

A. Tables 28 to 32 inclusive of this series contain the data resulting from analyses of samples of water collected from the Illinois river at the bridge across the Narrows, at Averyville, which is about three miles above the Court House at Peoria.

Table 28 has the data for the year 1897, the collections ranging from the 26th of April to the 27th of December of that year.

Table 29 for the year 1898, has the results of analyses of samples collected regularly each week throughout the
8645 year, beginning January 2 and ending December 26.

Table 30 has upon it the data resulting from analyses of waters taken at the same place, but during the year 1899. Regular weekly collections beginning January 3rd, and ending December 26th.

Q. How many samples a week were there taken?

A. Regular weekly samples, that means one a week.

Table 31 has a record of the results of analyses of samples collected at this same point during the year 1900. Regular weekly collections beginning January 2nd and ending December 26.

Table 32 has the results of the analyses of samples of water collected at the same place during the year 1901, beginning with January 2nd, and ending December 26, but during the first half of this year the collections were made monthly. During the second half of the year weekly collections were made.

Q. State professor, how the samples of water in these series were taken, at what depth below the surface?

A. The samples of water collected at Averyville were taken at midstream, at the bridge over the Narrows, and at a depth of one foot below the surface. They were taken in the manner heretofore indicated, the samples being collected in bottles expressly cleaned and shipped to the collectors for the pur-
8646 pose, and in accordance with printed instructions which accompanied each bottle. The collector recorded the date and such other facts concerning the conditions at that time prevailing as were called for by the instructions as to filling out the certificates, and which have hereinbefore been described.

Q. I now call your attention to tables 33, 34, 35 and 36, of this series and ask you to explain the character of the data contained in them?

A. Tables 33, 34, 35 and 36 contain the data obtained by the analyses of samples of water collected from the Illinois river at Havana, at a short distance above the town, just above the mouth of the Spoon river which enters on the right bank, and above the mouth of Quiver Lake which enters on the left.

Q. What periods do they cover?

A. The periods covered by these tables are as follows:

Table 33 the year 1897, regular weekly collections, beginning January 6th, and ending December 28th.

Table 34 covers the year 1898, regular weekly collections beginning January 4th, and ending December 27th.

Table 35 covers the results of analyses of water samples
8647 collected at this same point during the year 1899; collections beginning on January 3rd, and ending December 20.

Table 36 records the results of analyses of water collected at the same point, that is in the Illinois river at Havana, the collections beginning January 11 and ceasing December 24. Regular weekly collections between these dates.

Q. I now call your attention to tables 37 to 42 inclusive and ask you to state the character of the data contained in these tables?

A. Tables 37 to 42 inclusive contain the data of analyses of samples of water collected from the Illinois river at Kampsville, the collections being made just above the United States Dam.

Q. What periods were covered by them?

A. The periods covered by these tables is that including the years 1897 to 1902 inclusive.

Table 37 contains the data of analyses of samples collected during the year 1897, beginning January 12th and ending December 28th, regular collections, one each week.

Table 38 contains similar data for the year 1898; regular weekly collections beginning January 4th, and ceasing December 27th.

Table 39 of this series contains the data for the year 1899,
8648 regular weekly collections beginning January 3rd, and
ceasing December 20th.

Table 40 of this series contains data of similar sort, but for the year 1900, regular weekly collections beginning January 3rd; ceasing December 24th.

Table 41 contains similar data, but for the year 1901, regular weekly collections beginning January 7th and ceasing December 30th.

Table 42 of this series contains similar data for the same point, as for the five preceding tables, but for the year 1902, regular weekly collections beginning January 7th and ceasing December 29th.

Q. I call your attention now professor, to tables 43, 44, 45 and 46, and ask you to state the character of the data contained in those tables?

A. Tables 43,44, 45 and 46, contain the results of analyses of samples of water collected at Grafton during the years 1899 to 1902, inclusive, samples collected at a point about two miles within the mouth of the Illinois river, where ordinarily there is no mixing of the waters of the Mississippi with those of the Illinois.

Q. What do these tables contain?

8649 A. Table 43 contains the results of analyses of samples of water collected during the period December 31st 1898 to December 27, 1899, regular weekly collections throughout the year, of 1899, assuming the date December 31st, 1898, as pertaining to that year or series.

Table 44 of this series contains the results of analyses of samples of water collected at Grafton from the Illinois river at the point mentioned above, during the year 1900; regular weekly collections, beginning January 4th, and ceasing December 24th.

Table 45 contains the results of analyses of waters collected at the same point, but during the year 1901; collections beginning February 21st, and ceasing December 23rd, being collected somewhat irregularly. During the first half of the year monthly collections were made, but not for all of the months. During the second half of the year collections being made weekly.

Table 46 contains results of analyses of waters collected at the same point as indicated for the three preceding tables, but for monthly collections instead of weekly collections.

Q. I call your attention to tables 47, 48, 49 and 50, of this series and ask you to describe the data contained in those tables?

8650 A. Tables 47, 48, 49 and 50 contain the data of analyses of the waters of the Mississippi river at Grafton, the collections being made at a point about two miles above the mouth of the Illinois, where ordinarily no Illinois water mixes with the water of the Mississippi.

Table No. 47 contains the data for the year 1899, regular weekly collections throughout the year, beginning with December 31st, 1898 and ending December 20, 1899.

Table 48 contains the results of analyses of water samples collected at the same point as for table 47, but for the year 1900, regular weekly collections throughout the year, beginning January 4th and ending December 24th.

Table 49 contains data of analyses of waters collected at the same point, but for the year 1901; collections during the first half of the year made once a month, during the second half of the year each week.

Table 50 contains data of analyses of samples of water collected at the same point as for the three preceding tables, but for the year 1902, monthly collections.

Q. I now call your attention to tables 51 to 62, inclusive, of this series, and ask you to describe the data contained in them?

A. Tables 51 to 62 inclusive contain the data of the an-
8651 alyses of samples of water collected from the Mississippi
river at Alton during the years 1896, to 1900 inclusive. During 1897 and 1898 samples were collected at mid-stream but during the years 1899 and 1900 they were collected at five different cross-section points about one mile above the town of Alton and opposite to the new waterworks filter plant belonging to the city of Alton.

Table 51 contains data of analyses of samples of water taken from the channel of the Mississipi river oposite Alton for the year 1897, regular weekly collections beginning January 5th, and ending December 21st.

Table 52 contains similar data, that is data of analyses of waters taken at the same place during the year 1898, regular weekly collections throughout the year, beginning January 3rd and ending December 27th.

Table 53 contains the data of analyses of samples of water collected at a point 100 feet from the Illinois shore in the near vicinity of the Alton city waterworks, about one mile above the town, the data of this table are for the analyses of samples collected during the year 1899, regular weekly collections beginning January 5th and ending December 20th.

Table 54 contains similar data for water samples collected
at the same point, namely, 100 feet off the Illinois shore,
8652 but for the year 1900, regular weekly collections from
January 4th to December 24th inclusive.

Table 55 contains data of analyses of samples of water collected at the same general locality, but at one-fourth the distance from the Illinois shore, toward the Missouri shore, opposite the pumping station and filter plant of the Alton City water works, the table covers the data for the year 1899, regular weekly collections ranging from January 5th to December 20th inclusive.

Table 56 contains similar data for waters collected at the same point, namely one-fourth the distance from the Illinois shore at Alton, for the year 1900, the samples being collected each week from January 4th to September 5th, inclusive.

Table 57 contains the results of analyses of water samples collected at mid-stream in the line of this cross-section opposite the waterworks of the city of Alton, and about a mile above the town; the data of these tables referring to the analyses of samples collected during the year 1899, regular weekly collections from January 5th to December 20th, inclusive.

Table 58 contains similar data, the analyses of samples of water collected at this same point, namely, mid-
8653 stream in the Mississippi river opposite the Alton water-
works, but for the year 1900, regular weekly collections throughout the year from January 4th to December 24th inclusive.

Table 59 contains the data of the analyses of samples of water collected in the same cross-section line but at a point one-fourth distant from the Missouri shore, or three-fourths of the distance from the Illinois shore, this table having the data for the year 1899; collections beginning January 5th and ceasing after December 20th.

Table 60 contains the data of analyses of samples of water collected at the same point as those referred to in table 59, that is one-fourth distance from the Missouri shore at Alton, but for the year 1900; collections beginning January 4th and being made regularly each week thereafter until and including September 5th.

Table 61 of this series contains the results of analyses of samples of water collected in the same cross-section line, but at a point 100 feet from the Missouri shore; this table giving the data for the year 1899. Regular weekly collections throughout the year, beginning with January 5th, and ceasing after the collection upon December 20th.

Table 62 contains the data of the analyses of samples of
water collected at the same point as is referred to in my
8654 statement concerning table 61, but the collections were
for the year 1900 and extend from January 4th to December 24th, inclusive, regular weekly collections being made during this period.

Q. I now call your attention to tables 63 to 70 inclusive, and ask you to state the character of the data contained in these tables?

A. Tables 63 to 70 inclusive contain the results of analyses of samples of water collected from the Mississippi river at Quincy at a point above that at which any of the sewage of Quincy is discharged into the Mississippi river, and for the years 1897 to 1903 inclusive.

Table No. 63 contains the data of the analyses of samples of water collected from the Mississippi river at Quincy as indicated above, for the year 1897, the collections beginning upon February 15th and ceasing upon December 27th, regular weekly collections throughout the period.

Table 64 contains the similar data of analyses of samples collected at the same point during the year 1898; regular weekly collections beginning January 3rd and ceasing December 20th.

8655 Table No. 65 contains similar data for the year 1899, the collections beginning January 3rd and ceasing December 13th, but being irregular throughout that period, though mainly one a month.

Table No. 66 contains similar data for the same place for the year 1900; samples collected monthly, but not for all months in the year.

Table No. 67 contains results of analyses of samples of water collected at the same point for the year 1900; monthly collections, but not very regular throughout the year.

Table No. 68 contains similar results obtained during the year 1901, there being but six samples collected in that year, being distributed through various months of the year.

Table No. 69 contains similar data for the year 1902; samples collected sometimes irreguarly, but covering the year from January 13th to December 30th.

Table No. 70 of this series contains results of analyses of samples of water collected at the same point, but for the year 1903, the analyses covering, though somewhat irregularly, the period beginning January 3rd and ending August 17th of that year.

Q. I now call your attention professor, to tables 71, 72 and 73 of this series and ask you to explain the data contained in them?

8656 A. Tables 71, 72 and 73 give the data of analyses of samples of water collected from the Kankakee river at Wilmington, for the years 1897, 1899 and 1900.

Table No. 71, referring to the year 1897 contains the results of analyses of samples of water collected during the period ranging from January 8th to May 10th.

Table No. 72 contains data of analyses of samples of water collected at the same place, namely, Kankakee river at Wilmington, but during the year 1899, collections beginning June 5th, and ceasing December 26th, regular weekly collections throughout the period.

Table No. 73 contains similar data for samples of water collected at the same point in the Kanakakee river at Wilmington, but for the year 1900, weekly collections beginning January 1st and ceasing December 19th.

Q. I now call your attention, professor, to tables 74, 75, 76 and 77 and ask you to describe the data contained in those tables?

A. Tables 74, 75, 76 and 77 contain the results of analyses of samples of water collected from the Fox river at Ottawa, collection being made at a point a short distance above the aqueduct which carries the Illinois and Michigan canal over this stream.

8657 Table No. 74 contains the data for the year 1898, samples being collected each week during the period beginning March 1st, and ending December 26th.

Table No. 75 contains similar data of analyses of samples of water collected at the same point, but during the year 1899, the collections beginning May 29th, and ending December 28th.

Table No. 76 contains the data of analyses of samples of water collected at the same place but during the year 1900, collections beginning January 4th, and ceasing October 6th, being made regularly each week during that period.

Table No. 77 contains the data of the analyses of a small number of samples collected from the Fox River at the same point as indicated above, but during the year 1901, collections being made in August, September and October of that year.

Q. I now call your attention to tables 78, 79 and 80, and ask you to explain the character of the data contained in them?

A. Tables 78, 79 and 80 of this series contain data of analyses of samples of water collected from the Spoon river at Havana.

Table 78 contains data of the analyses for the year 1897, of samples taken at a point about half a mile within the mouth of the stream where there ordinarily is little danger of
8658 water from the Illinois mixing with the discharge from the Spoon. The samples were collected regularly each week throughout the year beginning on January 5th and ceasing on December 28th.

Table No. 79 gives similar data concerning samples of water collected at the same point, but during the year 1898, collections beginning January 4th and continuing regularly each week throughout the year, to and including December 27th.

Table No. 80 contains similar data of analyses of samples of water collected at the same point, but during the year 1899, the collections beginning January 3rd, and being made regularly each week up to and including May of that year, the last collection being made May 30th.

JUDGE SPRINGER: This concludes the explanation of the tables in this series.

MR. JEFFRIES: Now I move to strike out all of the explanation and testimony of this witness with reference to the tables which have been read in evidence, and from which he has been testifying,—being "Department of Chemistry, University of Illinois, A. W. P. tables No. 1 to 80 inclusive" for the same reason as contained in the objection to the introduction of the tables in evidence, and to their being incorporated as a part of the testimony of this witness or incorporated
8659 as a part of the testimony in this case.

For the further reason that they include chemical analyses of waters tributary to the Illinois river, and also waters that are not tributary to the Illinois river, while the conditions of the waters of those tributaries, or of those rivers other than the Illinois, are not in issue in this case.

IT IS HEREBY STIPULATED AND AGREED BY AND BETWEEN Counsel, that the samples of water taken by Raymond Hurd at Joliet from the Desplaines river, Denis J. Foley from the Illinois river at Ottawa, and John Egan and Richard

Cullen taken from the Missouri river at West Alton, and Chain of Rocks in the Mississippi river, and carried to the laboratory in St. Louis, were taken in the manner stated and required, as shown by Sanitary Districts' Exhibit No. 11 for identification, which contains instructions as to the manner the samples should be taken, and that all samples taken by these witnesses were taken in accordance with those instructions as near as may be, and said samples of water taken as aforesaid shall be considered as having been taken in the manner aforesaid, when testified to by the analyst who analyzed them.

8660 By agreement of counsel for complainant and defendants, and the Commissioner, an adjournment is hereby taken until Wednesday, October 28th, 1903, at same place, at 10:00 A. M.

8661 SUPREME COURT OF THE UNITED STATES.

State of Missouri,
vs.
State of Illinois
and the
Sanitary District
of Chicago
Original No.

869 The Rookery Building, Chicago, Illinois.

10:00 A. M., October 28, 1903. A continuance was here taken to November 9, 1903, same time and place, by consent of Commissioner and counsel for respective parties, upon motion of complainant.

Same place November 9, 1903, 10:00 A. M. A continuance was here taken to November 16th, 1903, same time and place, by consent of Commissioner and counsel for respective parties, upon motion of complainant.

8662 869 Rookery Building, Chicago, Illinois. 10:00 A. M., Monday, November 16th, 1903.

Continuation pursuant to adjournment. Present:

The Commissioner,
Mr. Jeffries,
Judge Springer,
Mr. Todd.

ARTHUR W. PALMER,

resumed the stand for further direct-examination by Judge Springer, and testified as follows:—

JUDGE SPRINGER: Before proceeding to the examination of Profesor Palmer, I desire to offer at this time in evidence, Defendants' Exhibit A entitled, University of Illinois Chemical Survey of the Water Supplies of Illinois, Preliminary Report, by Arthur William Palmer, S. C. D., Professor of Chemistry, published by the University, 1897.

This is offered now for identification and is marked Defendant's Exhibit A for identification.

This may be used by either party hereafter as evidence 8663 in the case, or it may be referred to by witnesses or counsel, without being printed as part of the record.

MR. JEFFRIES: Professor, this report was made to Andrew Sloan Draper, the President of the University of Illinois, was it?

A. Yes.

JUDGE SPRINGER: And is your official report as the head of this department of the University?

A. Yes, everything that goes to the trustees of the University goes through the President with us. I am a member of the University and everything goes to the President.

Q. At the conclusion of the hearing before the Commissioner on the 16th of October, the witness had briefly explained the contents of certain tables which had been read in evidence beginning with No. 1 of this series, this series being entitled, "University of Illinois, Department of Chemistry, A. W. P., 1 to 80 inclusive." Professor, I now call your attention to tables 1 to 4 inclusive, which contain the chemical examinations of water from Lake Michigan during the years 1897 to 1900 inclusive; will you please state what significance as a chemist, you attach to these tables of the examination of the waters of Lake Michigan?

MR. JEFFRIES: I object to the witness stating what 8664 significance these tables show for the reason that there is no evidence showing the place or point in Lake Michigan where the samples of water from which these analyses were made, were obtained.

JUDGE SPRINGER: I beg your pardon; he stated that in the brief explanation which he gave on the 15th and 16th of October, he stated where each sample was taken from.

MR. JEFFRIES: And I object for the further reason that there is no evidence showing the manner in which the samples were taken and no evidence showing the time of the analyses, after the taking of the samples.

JUDGE SPRINGER: On pages 9, 10 and 11, and subsequent pages of the testimony taken on October 16th, in the morning, you will find all of these matters fully set forth, where they were taken from, etc.

Q. (Last question read).

A. The data of the analyses show the general chemical character of the waters of Lake Michigan, and a comparison of the data for the different years with each other, and the averages for the different years with each other, show that the water of the lake is subject to no great variation as to the proportions of the various substances which are determined in the sanitary chemical analysis. They show that the water contains but a moderate proportion of mineral matters, that the organic
8665 matters are small in quantity as compared with many surface waters, and especially the proportions of nitrogen as free ammonia, as albuminoid ammonia, the total organic nitrogen, nitrites and also nitrates are present in a small quantity. The variations during the four years covered by the tables which have been read in evidence, namely, tables 1, 2, 3 and 4, of this series were in general, comparatively slight, and apparently were mainly caused by conditions which brought about variable discharges from the Chicago river, and from those sewers which empty directly into the lake and pass further out into the lake than they commonly do. They are also in part due to storms which stir up the sediment near the shore of the lake and near the cribs at which the intakes are located. The sediments being in the main such are natural to any considerable body of surface water, but including also a certain amount of refuse from the city and of dredgings from the Chicago river. The variations in no case vary considerably, and on the whole the water of the lake is to be considered as superior in quality to the water of all of the larger streams of Illinois and the vicinity.

The determinations of dissolved oxygen in the water of
Lake Michigan, upon samples drawn at the same time and
place as those which were subjected to the sanitary chem-
8666 ical analyses showed that the waters of the lake were at
all times fairly well charged, that is, generally saturated
with dissolved oxygen.

The data of the dissolved oxygen determinations are included in Defendants' Exhibit No. 24 for identification and are represented by the curves on plate marked "A. W. P. No. V" which has heretofore been placed in evidence.

Q. State whether the averages of these several tables are to be found at the bottom of each table?

A. They are.

Q. Professor, I now call your attention to tables in this series numbered 5 to 9 inclusive, which contain the chemical examinations of water from the Illinois and Michigan Canal, at Lockport. Please state what significance you attach as a chemist to these tables in reference to the waters at this place?

MR. JEFFRIES: I object to any conclusions being drawn by this witness from any of these tables numbered A. W. P. 1 to 80 inclusive, for the reason it is immaterial, irrelevant and incompetent, and for the same reasons stated by complainant in its objection to the introduction of the tables themselves.

A. The tables of analyses No. 5 to 9 inclusive, include the
results of examinations of samples of water taken from
8667 the Illinois and Michigan Canal at Lockport just before
it discharges into the Desplaines river. The periods
covered in these tables are the years 1897 to 1901 inclusive. Throughout the most of the time samples were taken regularly once each week, but during the earlier part of 1901 samples were collected but once a month.

In addition to the data in these five tables, I have made use of the averages for the year 1896; that is for samples of water collected regularly once a week from the Illinois and Michigan Canal at Lockport, during the year 1896, which analyses or the data resulting from them, are recorded in the preliminary report of the chemical survey of the waters of Illinois, which has heretofore been presented for identification as "Defendants' Exhibit A for identification."

The fluid pumped from the west fork of the south branch

of the Chicago river into the Illinois and Michigan Canal at Bridgeport flows sluggishly for a distance of about 29 miles to Lockport, where the first discharge from the canal into the Desplaines river occurs, the discharge being occasioned by the use of canal water as hydraulic power to run the Norton Mills situated at that point. Four miles further down the water from the canal discharges directly into the Desplaines river in the upper part of the town of Joliet, the canal at this point
8668 crossing the river by means of a dam and pool. Before the opening of the Chicago main drainage channel the liquid pumped into the old canal at Bridgeport constituted the major part of Chicago's sewage; it contained then and it still contains both house sewage and manufacturing wastes, the latter including drainage and refuse from stock yards, rendering establishments, soap factories, metallurgical and chemical works, gas works, and so on. Ordinarily no appreciable dilution and no notable additional pollution occurs between Bridgeport and Lockport, but in certain seasons, water from various ditches, and formerly also from the Desplaines river in excessive freshets flowed into the canal and diluted the contents of the same. The concentration of this liquid, flowing in the canal and the nature of the manufacturing and other wastes contained in it, is such that no very considerable change in the quantity or the character of the organic matters appear to take place between Bridgeport and Lockport, a fact demonstrated by comparative analyses made for the sanitary district of Chicago which have heretofore been read in evidence in this case, and also by examinations made on behalf of the State Board of Health, which also have been put in evidence in this case.

The analyses of the water of the Illinois and Michigan Canal at Lockport, serve to show the character of the liqud as it is discharged into the Desplaines valley in the main at
8669 Lockport, but in part at Joliet, four miles further down. The results are given in the details above referred to, and in the preliminary report also referred to above. The data reveal notable variations generally in April and March, the usual season of freshets, but for most of the year they show a somewhat remarkable uniformity in the proportions of organic matters.

Q. Have you prepared any tables of averages based upon the chemical analyses which you made of the waters of the Illinois and Michigan Canal at Lockport during the period under consideration?

A. I have.

JUDGE SPRINGER: Let these be referred to hereafter as "Defendants' tables of averages A. W. P. Nos. 1 to 15 inclusive."

Q. Will you please state what the averages were as appears by table No. 1 of this series of tables of averages?

MR. JEFFRIES: I object to the introduction of these tables of averages, or to the witness stating what they are for the reason that a table of averages does not directly represent conditions that exist at any one time or at all times during the year, and for the reason that they are deceptive in that they fail to disclose conditions that have not occurred and which are of as much importance so far as the issues in this case are concerned as conditions that are disclosed by those tables.

8670 JUDGE SPRINGER: Counsel for defendants suggest that we will only deal with the conditions shown in the tables, the things that are not in these tables are too numerous to be considered.

MR. JEFFRIES: I suggest that my objection does not go to conditions that are not in the tables, but to conditions that are in the tables, and the conclusions that may be drawn from a table of averages are as deceptive as the tables of averages themselves, for the reason that the conditons of the water for sanitary purposes cannot be averaged and should not be averaged; that conditions might exist and do exist of an abnormal character, as shown by the tables, which should not be measured by a general average drawn from those tables.

JUDGE SPRINGER: I suggest that this objection goes simply to the weight of the evidence and not to its admissibility.

Q. Now proceed, professor? (Question repeated).

A. Table No. 1 of this series contains the averages of the analyses of the waters of the Illinois and Michigan Canal collected at Lockport, for the years 1896, 1897, 1898 and 1899, and the general average for the four years period.

Q. Will you read that table No. 1 in evidence?

A. Table No. 1 of averages, is as follows:

8671

DEFENDANTS' TABLE OF AVERAGES NO. 1.—A. W. P.

TABLE III.

CHEMICAL EXAMINATION OF THE WATERS OF THE ILLINOIS AND MICHIGAN CANAL AT LOCKPORT, BEFORE THE OPENING OF THE CHICAGO MAIN DRAINAGE CHANNEL. YEARLY AVERAGES. PARTS PER MILLION.

Year	Chlorine	Oxygen Consumed.			Nitrogen as Ammonia.				Organic Nitrogen.			Nitrogen as	
						Albumoid Ammonia.							
		Total	By Dissolved.	By Suspended Matter.	Free Ammonia	Total	Dissolved	Suspend'd	Total	Dissolved	Suspended.	Nitrites	Nitrates
1896	119.1	39.2	14.7	24.5	14.99	2.55	1.17	1.38	5.17	2.19	2.98	.007	.195
1897	115.4	38.3	18.1	20.2	12.4	2.72	1.34	1.38	4.94	2.31	2.63	.039	.235
1898	116.8	42.2	19.1	23.1	12.7	2.86	1.48	1.38	5.62	2.5	3.02	.072	.417
1899	135.2	39.5	21.2	18.3	13.9	2.93	1.44	1.51	5.56	2.84	2.72	.013	.317
Av'e	121.6	39.8	18.3	21.5	13.5	2.77	1.36	1.41	5.3	2.46	2.84	.033	.29

8672 Q. Now what significance do you attach to these tables and to the tables of averages which has just been read in evidence, from a chemical standpoint?

MR. JEFFRIES: The question is objected to for the same reasons stated in the previous objection.

A. Inspection of the yearly averages which appear in table No. 1 of this series shows that up to the time of the opening of the Chicago main drainage channel there were in most respects but slight variations from year to year, such changes as did occur being in the direction of a small but constant increase of the nitrogenous organic matter.

Examination of the data of the analyses for the year 1900, which appear in table 8, and for the year 1901, which appear in table No. 9 reveal much greater and more frequent variations than occurred before the opening of the Chicago main drainage channel. The averages of the analyses of the waters of the Illinois and Michigan Canal at Lockport for the years 1900 and 1901 appear in tables of averages No. 2, A. W. P.

Comparison of the averages for the two periods shows that the relative proportions of organic matters were considerably reduced as a result of the diversion of a part of the sewage, and the new drainage channel, although the proportions of nitrogen as free ammonia became greater than before, a result

8673 which may be due to the effect of the greater dilution in facilitating the more speedy oxidation of the organic matter. The variations are mainly due to the fact that at times when the lake is high, or the discharge from the drainage canal at the controlling works is reduced comparatively pure lake water backs up into the south fork of the Chicago river in such volume that a more dilute sewage than usual is raised by the pumps at Bridgeport into the Illinois and Michigan canal, while ordinarily inasmuch as the south fork is not yet flushed out, the liquid pumped into the old canal, that is, the Illinois and Michigan Canal, still consists mainly of the comparatively concentrated sewage from the stock yards district.

As compared with the analyses of the waters of Lake Michigan as given in tables 1 to 4, the waters of the Illinois and Michigan canal of course show evidence of the enormous quantities of refuse matters which are discharged into the Chicago river, and which thence pass into the Illinois and Michigan Canal, this being revealed by the very much greater proportions of organic matters contained in the canal water as compared with those contained in the lake water.

Q. As you have referred to table No. 2 of these averages, you may now read that table in evidence.

8674 MR. JEFFRIES: The same objection as to the previous table.

A. The table is as follows:

8675

DEFENDANTS' TABLE OF AVERAGES NO. 2.—A. W. P.

TABLE IV.

CHEMICAL EXAMINATION OF THE WATERS OF THE ILLINOIS AND MICHIGAN CANAL AT LOCKPORT, AFTER THE OPENING OF THE CHICAGO MAIN DRAINAGE CHANNEL.

YEARLY AVERAGES. PARTS PER MILLION.

Year.	Chlorine.	Oxygen Consumed.			Nitrogen as Ammonia.				Organic Nitrogen.			Nitrogen as	
						Albuminoid Ammonia.

8676 **JUDGE SPRINGER:** I now call your attention to tables in this series Numbered 10 and 11, which contain the results of chemical examinations of water from the sanitary canal at Lockport, will you please state whether you made any averages of those two tables?

A. I did.

Q. Will you read those averages into the record at this time as a part of your testimony?

MR. JEFFRIES: I will object to the reading of the tables of averages in question into the record as a part of this witness' testimony for the same reason stated in my objections to the reading of the previous tables of averages into the evidence, and I object to the witness drawing any conclusions or stating any conclusions from these tables, for the same reasons stated in my objection to the reading of the tables of averages and the introduction of the tables themselves into the record.

A. The table of averages is No. 3, A. W. P., and is as follows:

8677

DEFENDANTS' TABLE OF AVERAGES NO. 3.—A. W. P.

TABLE V.

CHICAGO MAIN DRAINAGE CHANNEL, LOCKPORT. YEARLY AVERAGES. PARTS PER MILLION.

Year	Chlorine	Oxygen Consumed.			Nitrogen as Ammonia.				Organic Nitrogen.			Nitrogen as	
		Total	By dissolved	By suspended matter	Free Ammonia	Albuminoid Ammonia.			Total	Dissolved	Suspended	Nitrites	Nitrates
						Total	Dissolved	Suspend'd					
1900...	15.6	7.65	5.12	2.53	1.593	.421	.183	.238	.985	.442	.543	.006	.25
1901...	14.5	9.29	6.76	2.53	1,715	.422	.238	.184	.99	.532	.58	.023	.18
Av'e..	15.	8.47	5.94	2.53	1.654	.421	.210	211	.987	.486	.5	.015	.21

8678 Q. **JUDGE SPRINGER:** Now what significance do you attach as a chemist to these analyses as exhibited by the tables to which your attention has been called, and the table of averages?

A. The analyses of samples of water collected from the sanitary canal or the Chicago main drainage channel at the Bear Trap dam at Lockport, have been read in evidence in tables 10 and 11, and they show notable variations. The variations

which appear in these analytical data are due in the main to variations in the volume of flow in the drainage channel, caused partly by differences in the lake level, partly by the partial closing of the gates or the raising of the Bear Trap dam at Lockport and also at certain times by the overflow of water from the Desplaines river at the spillway into the main drainage channel itself. Further, they are caused in part by variations in the pumping at Bridgeport for when the Bridgeport pumps are not in operation a portion of the contents of the south fork enters the south branch of the Chicago river, and passes thence into the main drainage channel, while when the pumps at Bridgeport are kept in operation practically all of the sewage of the south fork is discharged into the Illinois and Michigan canal, and enters the Desplaines river below the point of discharge from the main drainage channel. Comparison of the figures in table of averages No. 3, with the figures appearing
8679 in tables of averages Nos. 1 and 2, show that the waters discharged through the sanitary canal are far more dilute than the waters discharged through the Illinois and Michigan canal, that is, the proportions of the various significant constituents notably those of the nitrogenous constituents, are very much less in the waters of the sanitary canal or main drainage channel, than they were and than they are in the waters of the Illinois and Michigan canal.

MR. JEFFRIES: I move to strike out all that the witness has said with reference to the variations in the analyses being caused by change in the lake level and changing quantities of water passing through the Bear Trap Dam, for the reason that they are not conclusions based upon and drawn from the tables themselves, and therefore not responsive to the question; and for the further reason that there is no evidence introduced along with the tables and shown on the tables, which gives variations in the lake level and the volume of water flowing through the Bear Trap Dam, so as to be comparable with the data contained in the tables of averages themselves.

JUDGE SPRINGER: I will state that the data to which counsel has referred will be given later by other witnesses, but this witness may submit any data that he has upon the
8680 subject bearing upon the points to which counsel has referred.

MR. JEFFRIES: I suggest that this data be furnished counsel before this witness leaves the stand, that is to be introduced by other witnesses, as well as by this witness, so that we may be able to cross-examine on this proposition.

JUDGE SPRINGER: We will furnish you with as much of it as we can.

Q. Have you any plates or tables which will exhibit or show the volume of water in the drainage canal at the various periods covered by these tables?

A. I have.

Q. You will please submit them. Have these been put in evidence heretofore?

A. They have, and are included in the series of plates A. W. P. Nos. V to XLV inclusive, heretofore read in evidence.

Plate VI of this series gives the flow in the Illinois and Michigan Canal at Bridgeport, the Desplaines river at Riverside; the Chicago main drainage channel at Lockport, at the Bear Trap Dam, the Desplaines river at Joliet, where all these various bodies of water have come together, and in the upper part of the plate there are shown curves which reveal the relative proportions of water discharged by the sanitary canal at the Bear Trap Dam, discharged over dam No. 1 at Joliet, 8681 and the volume of water discharged over the dam at Kampsville, that is the quantity of water discharged by the Illinois river at the point 31 miles within its mouth.

Plate No. VII of this series, gives by means of curves a comparison of the relative volume of water discharged by these various streams or agencies at the same points, but for the year 1901. With respect to these plates I may say that the curves have been prepared to show graphically the figures representing the mean daily flow of each one of these streams at the point referred to, except that for convenience, the weekly flow of the Desplaines river at Joliet, and the mean weekly discharge of the sanitary canal at the Bear Trap have been represented. Upon the lower portion of each plate there appear curves representing the discharges of the sanitary canal the Illinois and Michigan canal, the Desplaines river at Riverside instead of Lockport, as printed on the plate; the Desplaines river at Joliet, these all being stated in cubic feet per minute; the upper part of each plate, the comparison between the discharges of the Desplaines river at Joliet and of the sanitary canal at the Bear Trap Dam, with the discharge of the Illinois river over the Kampsville dam, is represented in cubic feet per second, for convenience in getting the curves on a reasonably convenient or small plate.

8682 MR. JEFFRIES: I move to strike out the testimony of this witness and the conclusions that he draws from the plates in question, and the conclusions in particular with reference to the volume of water passing down the various streams at the given points, and his testimony with reference to the change and variations of the lake level and of the variations of the water in the main drainage canal, for the reason that the witness has not qualified himself in the evidence as a hydraulic engineer.

JUDGE SPRINGER: From what source did you obtain those facts?

A. The data from which these curves have been drawn so far as it concerns the sanitary canal, the Desplaines river at Riverside, the Illinois and Michigan Canal at Lockport and the Desplaines river at Joliet, were furnished to me by Mr. Isham Randolph, the engineer for the Sanitary District of Chicago. The data from which the curves representing the flow over the Kampsville dam were made, were furnished me by the Assistant U. S. Engineer who is in charge of that dam, namely, Mr. C. V. Brainard, and these were furnished me as part of the data gathered in my study of the water supplies of Illinois, as part of the work of the State Water Survey, which was in my charge.

MR. JEFFRIES: To the last answer of the witness I renew my motion to strike out, for the reasons stated.

8683 Q. Now you stated that you obtained part of this data from Mr. Isham Randolph—that part of the data will be put in evidence by Mr. Randolph when he is put on the stand, the data in reference to the flow of the Illinois river at Kampsville. That will be offered in evidence at a subsequent place in the proceedings.

MR. JEFFRIES: I still move to strike out the conclusions drawn by this witness from the table for the reason that there is no evidence to show that the information obtained by this witness from Mr. Randolph or from Mr. Brainard or from the other sources represent and is the same that will be testified to by them when they go upon the stand.

JUDGE SPRINGER: When Mr. Jeffries objected to your testimony on acount of the absence of data in reference to the flow of the water, you were proceeding to explain these tables now before you. Have you any further explanation to submit in regard to them?

A. Yes. These were at this time referred to merely in answer to the previous objection of counsel for complainant, namely that the discussion of the absence of the data of analyses was useless because there was no consideration given, to questions of variations in flow in the streams in question. I
have the data in figures upon which the lines of these
8684 plates are based, and they will be introduced in evidence
later.

Q. Have you any further explanation to be made of the chemical results of these examinations at these points?

A. Not at present, although they will be referred to later when we come to consider the problems involved in the present controversy.

Q. I call your attention now to tables Nos. 12, 13 and 14, which contain the chemical analyses of water from the Desplaines river at Lockport. Is that designation correct? At Lockport or was it at Riverside?

A. No this is at Lockport.

Q. Did you prepare any averages of those tables?

A. The only averages of these tables which I prepared appear at the bottom of each table. Further comparative averages of the data in these tables were not made.

Q. What do these tables indicate as to the chemical condition of the waters in the tables to which your attention has just been called?

A. Well the Desplaines river at Lockport is a small stream with an exceedingly variable flow. Variations are shown graphically upon plates VI and VII mentioned above and heretofore
read in evidence. Above Lockport the Desplaines re-
8685 ceives the sewage from various suburban towns. For the
purposes of this investigation an effort was made to have samples of water collected beside the old stone bridge which crosses the river near Lockport at a point above which the dis-

charge from the Illinois and Michigan canal ordinarily enters the stream. Through some misunderstanding of the collectors samples were not always collected at a point which was not reached by the discharge from the Illinois and Michigan canal; consequently there are very considerable and abnormal variations in the data of the chemical analyses, particularly for the years 1897 and 1898. In the years 1899 and 1900 the samples were collected at a point not reached by the discharge from the Illinois and Michigan canal and the data are more uniform in character and more strictly representative of the conditions of the water in this stream except in times of freshet or of prolonged wet weather. The waters of the upper Desplaines have but a slight effect upon the sewage flowing past Joliet.

Q. For what reason?

A. Because of their inconsiderable volume.

Q. I now call your attention to tables of this series Nos. 15 and 16, which contain chemical examinations of water 8686 in the Desplaines river at Joliet during the times indicated heretofore. Will you please state whether you have prepared averages of these other than those contained at the bottom of the tables themselves?

A. I have.

Q. Will you present that table of averages and give its number?

A. The table of averages is No. 4, A. W. P. and brings together the yearly averages of results of analyses of samples of water collected from the Desplaines river at Dam No. 1 in the upper part of the town of Joliet, the averages covering the years 1899, 1900 and 1901. Those for the later year including two sets, representing analyses of one set of samples collected at the east side of the stream at the point given above, and the other including the analyses of a set of samples collected at the other or west bank of the stream.

Q. Will you present that table?

A. Yes, the table No. 4 is as follows:

8687

TABLE VI.

DEFENDANTS' TABLE OF AVERAGES NO. 4.—A. W. P.

CHEMICAL EXAMINATION OF THE WATER OF THE DESPLAINES RIVER AT JOLIET. YEARLY AVERAGES. PARTS PER MILLION.

Year	Chlorine	Oxygen Consumed.			Nitrogen as Ammonia.				Organic Nitrogen.			Nitrogen as	
		Total	By Dissolved	By Suspended Matter	Free Ammonia	Albuminoid Ammonia.			Total	Dissolved	Suspended	Nitrites	Nitrates
						Total	Dissolved	Suspend'd					
1899	105.7	28.5	16.2	12.3	14.92	2.195	.831	1.364	4.502	1.732	2.77	.01	.208
1900	30.4	11.1	7.3	3.8	2.971	.707	.402	.305	1.574	.83	7.44	.031	.31

Mean	22.2	9.1	7.0	2.1	2.492	.418	.243	.175	.96	.544	.416	.03	.296

8688 Now, what explanation can you give of the chemical condition of the waters at these places—you may state first whether the waters at this place contain waters from the Illinois and Michigan Canal, the drainage canal and the Desplaines river?

A. I would like to make a fuller explanation of the average first. I wasn't quite through.

Q. Proceed then.

A. The detailed data of the analyses for the years 1899 and 1900 have not been given in this series of tables, but appear in the tables 1 to 80, inclusive, heretofore read in evidence, said tables being included in the report of the testimony given on behalf of the Sanitary District of Chicago.

JUDGE SPRINGER: Those tables are known as Streams Examination Report, and are consequently not repeated in this series.

A. At this point, namely, Joliet, which is about four miles below Lockport, the I. and M. canal crosses the Desplaines river by means of the valley or basin formed by Dam No. 1 which is located in the upper part of the town; the canal from this point on passing down the side, the west or north bank of the river to its terminus at LaSalle, approximately 100 miles from the beginning of the canal at Bridgeport. It is between this dam

and Lockport that the discharges from the Illinois and
8689 Michigan canal, and since January, 1900, the discharge
from the drainage channel have entered the Desplaines valley and mixed with the waters of the Desplaines river; consequently this is the point at which the initial effect of the discharge of Chicago sewage is at the maximum. Prior to the opening of the drainage channel the seasonal variations in the composition of the water or in the proportions of the various chemical constituents at this place were considerable because of the variations in flow of the diluting waters of the upper Desplaines, during a large or greater part of the year especially the summer and autumn seasons, the dilution of the concentrated sewage discharged from the old canal, that is, the Illinois and Michigan canal is very slight; but in the earlier or flood seasons of the year the flow in the Desplaines at this point would occasionally amount to three or four hundred thousand cubic feet a minute and the dilution of the sewage be correspondingly great; that is, about 10 to one. In the summer season, when the natural flow in the upper Desplaines generally dwindles to almost nothing, there is practically no dilution. The 36,000 cubic feet per minute of sewage raised by the pumps at Bridgeport, in the Illinois and Michigan canal and discharged at Lockport and Joliet constituting the entire flow. Indeed, the river bed below the dam at Joliet would at times be almost entirely dry, the flow for some distance below this point being
8690 entirely carried by the Illinois and Michigan canal. Since
the opening of the drainage channel the volume of water passing this point is much more uniform. The effect of the dilution of this sewage is seen in the very great difference between the data of analyses of samples taken during the year 1899 or before the drainage channel was put in operation and those taken for the years 1900 and 1901, the year immediately subsequent to the opening of the sanitary canal or main drainage channel. During the year 1900 there were found great variations in the proportions of the various constituents of the water. These variations were in part due to seasonal variations of flow in the upper Desplaines river, and in part the result of variations in the flow in either the Illinois and Michigan canal or the main drainage channel or both. If then for any reason the flow in the channel—the drainage channel is reduced or stopped by

manipulation of the gates at Lockport, sewage accumulates in the Chicago river and the discharge into the Desplaines consists then chiefly of the more concentrated sewage of the Illinois and Michigan canal and when the gates are again opened a much less diluted mixture of the accumulated sewage is in time discharged by the main drainage channel. However, many of the variations hitherto noted were due to incomplete mixing of the
several bodies of sewage and water which go together in
8691 this vicinity, a fact that is shown particularly by the re-
sults obtained from the analyses of the two series of samples collected during the year 1901. During this year a sample was taken at each side of the river at Dam No. 1, at Joliet, the averages for the year, and also the mean for the two series of analyses are shown in table No. 4 of averages.

Comparison of the averages for 1900 and 1901 with those for 1899, makes evident the great difference in concentration of the sewage passing Joliet after the opening of the main drainage channel. Most of the sewage of Joliet enters the stream below the point at which Joliet samples were collected.

Comparison of some of the figures in the tables of averages will serve to illustrate or call attention to the conditions referred to above; thus, the average proportion of chlorine in this water in the year 1899 was 105.7 parts per million, while in 1900 the average was 30.4. In 1901 the samples at the east side of the stream gave as an average for the chlorine content, 29.7 parts per million, and for the west side of the stream an average of 14.7 parts per million. The mean for the two series being 22.2 parts of chlorine per million.

The oxygen consumed shows a similar decrease after the
opening of the main drainage channel; thus the average
8692 for the year 1899 for the total oxygen consumed was 28.5
parts per million, and for 1900 11.1 parts per million; for 1901 east side, 9.7 parts per million, and the west side 8.6 parts per million. The average or mean for the two series being 9.1 parts per million.

Similar conditions manifest themselves on comparison of the averages representing the content of nitrogen as free ammonia, that is, for the year 1899, the average proportion was 14.92 parts of nitrogen as free ammonia per million, and for the year 1900 there were but 2.971 parts of nitrogen as free ammonia per million. For the year 1901 on the east side the average was 3.355 parts per million and for the west side 1.629 parts per million, the mean for the two series for 1901 being 2.492 parts per million; thus, the proportion of free ammonia for the year 1899 of 14.92 more than five times as great as the proportions found in the year 1900, namely, 2.971, and for the year 1901, which was 2:492.

The nitrogen as albuminoid ammonia, both the total, the dissolved and the suspended show a similar diminution in proportion on comparison of the data for the year 1899 with the data for the years 1900 and 1901. The total albuminoid ammonia for the year 1899 being 2.195, while for the year 1900 it was .707, and for the year 1901, for the east side it was
8693 .478, and for the west side .359, the mean for the two being .418. The nitrogen as albuminoid ammonia was for 1899, .831; for 1900, .402; for 1901, east side, .269; west side, .218; the mean for the two, .243. Nitrogen as albuminoid ammonia derived from suspended matters was for 1899, 1.364; for 1900, .305; for 1901, east side, .209; west side, .141; mean for the two being .175.

Total organic nitrogen shows similar variations for the year 1899, which was 4.502; for the year 1900, 1.574; for the year 1901, 1.05; for the east side and for the west side, .87; the mean for the two being .96. The organic nitrogen contained in dissolved substances was for 1899, on the average 1.732; for 1900 it was .83; for the year 1901, for the east side, it was .574; for the west side .515; the mean being .544.

Organic nitrogen in suspended matters was for 1899, 2.77; for 1900, .744; for the year 1901, east side, .476; west side .356; the mean being .416.

Nitrogen as nitrites for the year 1899 was .01; for the year 1900, .031; for the year 1901, east side, .031; west side, .03; the mean being .0305.

Nitrogen as nitrates for 1899 was .208; for 1900, .31; for 1901, east side, .334; west side, .268; the mean being .296.

Adjourned until 2:00 p. m., same day, Nov. 16, 1903.

8694 2:00 p. m., Monday, November 16th, 1903. Continuation pursuant to adjournment.

Present, the Commissioner and same counsel representing the respective parties.

PROF. ARTHUR W. PALMER,

resumed the stand for further direct-examination, by Judge Springer, and testified as follows:

Q. I now call your attention, Professor, to tables 17 and 18, 19 and 20, of this series, which give the chemical examinations of water in the Illinois river at Morris. Will you please state whether there were any averages made by you based upon those tables?

A. Averages for the first six months, second six months and the year, for the tables 17 to 20, inclusive, appear at the bottom of the respective tables, but in addition to these I have prepared a table of averages, in which these yearly averages are brought together for the purpose of comparison. This table of averages is known as Defendants' Table of Averages No. 5, A. W. P.

Q. Will you please read that table in evidence?

A. Table of Averages, No. 5, is as follows:

8695

DEFENDANTS' TABLE OF AVERAGES NO. 5.—A. W. P.

TABLE VIII.

CHEMICAL EXAMINATION OF THE WATERS OF THE ILLINOIS RIVER AT MORRIS.

8696 Q. Now, what significance do you attribute to these tables, and the table of averages to which you have just referred and which you have read in evidence?

A. Morris is the first station upon the Illinois river proper. At this point the waters of the stream consist of an incomplete mixture of the sewage laden waters of the Desplaines river with the waters of the Kankakee. Prior to the opening of the drainage channel the Chicago sewage discharged into the Desplaines river experienced no considerable dilution before getting the waters of the Kankakee, except when the Desplaines itself was in flood. This, however, was rarely the case at times other than those of the usually short spring freshets. When the Kankakee was in flood, the dilution at this point was of course correspondingly great, as much as 50 to 1; the average dilution for the year being about ten to one, but ordinarily in the summer and autumn the dilution would probably rarely exceed two or three to one, and often fall far short of this. Since the opening of the drainage canal the flow in the lower Desplaines is far more uniform and the average is just about equal to the average flow of the Kankakee, which is about 300,000 cubic feet per minute.

Q. The volume of water therefore added after the opening of the canal to the stream was as great as the volume

8697 which existed before at the mouth of the Desplaines river?

A. Yes, but the average through the two canals is much more uniform throughout the year, while the figure referred to with respect to the Kankakee is an average for the year, and includes volume ranging from a very small minimum flow elsewhere stated in the testimony, and the exceeding great flow of the spring freshets. That is to say, the volume from the Kankakee varies greatly at the different seasons, while the flow in the Desplaines due to the discharges from the main drainage channel and the Illinois and Michigan canal is fairly uniform throughout the year, considering the details of the analyses which appear in tables 17 to 20, inclusive, considerable variations appear, which, however, are not entirely due to variations in the volume of water flowing, but are in part due to the fact that at this point the mixing of the waters from the two general sources, namely, the Desplaines river and the Kankakee river, are quite incomplete, so that individual analyses consequently appear to vary considerably more than the mean composition of this in-

complete mixture warrants, but it is not likely that the variations thus occasioned are for this point sufficiently great to seriously affect the yearly averages and the comparisons instituted between them. The table of averages—this table No. 5,
8698 A. W. P., contains the yearly averages of analyses of the
waters of the Illinois river at Morris for the year 1896, which average is derived from the data in the preliminary report of the chemical survey of the waters of the state, heretofore mentioned and introduced for identification.

The averages for the year 1897, which appear in table No. 17 averages for the year 1898, the detailed analyses for which appear in table No. 18; averages for the year 1899, the detail analyses for which year appear in table No. 19, and averages for the year 1900, the detail data for which appear in table No. 20, so we have thus averages for four years preceding the opening of the main drainage channel, and for one year subsequent thereto. The general averages made up from these yearly averages, and hence representing the four years period before the opening of the Chicago main drainage channel, are as follows:

Chlorine,	44.4
Oxygen consumed,	15.6
Oxygen consumed by dissolved substances,	11.2
Oxygen consumed by suspended matters,	4.1
Nitrogen as free ammonia,	5.585
Nitrogen as albuminoid ammonia, total,	.97
8699 Dissolved,	.499
Suspended,	.387
Total organic nitrogen,	1.8625
Organic nitrogen in dissolved matters,	1.05
Organic nitrogen in suspended matters,	.756
Nitrogen as nitrites,	.0965
Nitrogen as nitrates,	1.0665

The averages for the year 1900 are as follows: Chlorine 23.1, a little more than half as much as the average for the four preceding years, and about one-third as much as for the year 1899, the year immediately prior to the opening of the drainage channel.

The oxygen consumed, the average for the year 1900, was 12.3, as against 15.6, the average for the four preceding years.

Oxygen consumed by dissolved matters, 6.7 as against 11.2, the average for the two preceding years, namely, 1897 and 1899, the only years for which we have the determinations of oxygen consumed by dissolved matters.

The oxygen consumed by suspended matters for the year 1900 is 5.6, as against 4.1, the proportions required of the
8700 average for the two years preceding, that is, the year 1897 and the year 1899.

Free ammonia for the year 1900, the average was 2.075, as against 5.585, the mean for the four preceding years.

The nitrogen as albuminod ammonia, total, .535, as against .97 the average for the four preceding years. The albuminoid ammonia derived from dissolved substances .269 for 1900, as against .499 the average for the years 1897 and 1899.

The albuminoid ammonia derived from suspended matters for 1900 was .2666 as against .387, the average for the years 1897 and 1899.

Total organic nitrogen for the year 1900 was 1.162 as against 1.3625, the average for the four preceding years.

The organic nitrogen contained in dissolved matters was .631 as against 1.05, the average for the years 1897 and 1899.

The organic nitrogen in suspended matters was .531 for 1900, as against .756, the average for the years 1897 and 1899.

Nitrogen as nitrites, the average for 1900 was .108, while the average for the four preceding years was .0965, and
8701 for the year 1899, was .026.

Nitrogen as nitrates, average for 1900 was .717, while the average for the four preceding years was 1.0665.

It is evident that at this point the proportions of chlorine and of organic matters as represented by the oxygen consumed and nitrogen in the form of free ammonia and albuminoid ammonia, the total organic nitrogen, have been considerably less in the waters of the Illinois in the year 1900 than they were during the four preceding years. On the other hand, the nitrogen as nitrites was present in the water of the Illinois river at Morris in more considerable proportion in the year 1900 than in 1899, or than it was on the average during the four preceding years.

Nitrogen as nitrates was present in greater proportion in the year 1900 than in the year 1899, or the average for the four years preceding the opening of the Chicago drainage canal was greater than the proportion contained during the year 1900.

Q. How do you account for these facts as to the nitrates and the nitrites?

A. The nitrites in the waters of the Desplaines river at Joliet have been considerably greater in proportion since the opening of the Chicago main drainage channel than they were prior to that opening, and the same is true at Morris. 8702

It is evident then, that such agencies as bring about the oxidation of the organic matters through ammonia to nitrites, and finally to nitrates, are fully as effective since the sewage has been more extensively diluted at and near Chicago. The fact that the nitrites are now found in greater quantity at Joliet and at Morris indicate that the nitrifying action going on in the river is more active at a point nearer to Chicago; that is, that the oxidizing influences at work upon the organic matters in the waters of these streams are more efficient now nearer to Chicago, this undoubtedly being one of the results of the greater dilution of the sewage with comparatively pure and oxygen saturated lake Michigan water.

Q. I call your attention now to tables in this series numbered 21, 22 and 23, which contain the chemical examinations of water from the Illinois river at Ottawa. Did you prepare any table of averages covering these three tables?

A. I did.

Q. Will you read that table?

A. The table numbered 6, is as follows:

8703

DEFENDANTS' TABLE OF AVERAGES NO. 6.—A. W. P.

TABLE IX.

8704 Will you please explain what is illustrated by these tables and the table of averages based upon them?

A. Now table 6 of this series contains a series of averages of analyses of the waters of the Illinois river at Ottawa and also averages of the series of analyses of the water of the Fox river at Ottawa. The latter we shall not discuss until we come to the consideration of the tributaries.

The collections from the Illinois river at Ottawa were made at a point about a mile above the mouth of the Fox and above the point where the sewage from the town of Ottawa and some discharge from the Illinois and Michigan Canal enters the stream, the detail data are as indicated above, included in tables 21, 22 and 23.

The analyses show the changes which take place during the flow of 24 miles from Morris to Ottawa, without further dilution and without notable addition to impurities, but the mixing of the discharges from the Desplaines and the Kankakee is not yet complete at this point, and some of the variations of the individual analyses are due to this cause. It is to be noted that at this point the nitrites are found in the waters of the Illinois river in greater proportions than at any other point along its course, which fact taken into consideration with the other indi-
8705 cations of the analyses, shows that it is in this stretch of the river that the final oxidation processes which convert the organic matters of the sewage into innocuous mineral substances, the free ammonia, the nitrites and the nitrates and so on, are most active and effective.

Comparison of the averages for the Illinois river at this point for 1899 with those for 1900, and the few for 1901, show how great was the dilution effect of the flow of the Chicago main drainage channel, thus the chlorine for the year 1899 averaged 59.5—this is at Morris—while for the year 1900, it was 21.3.

The total oxygen consumed was in 1899, 11.3; in 1900, 8.6.

Oxygen consumed by dissolved substances in 1899, 10.5, in 1900, 6.9.

That required by suspended matters was in 1899, 1.13, in 1900 it was 1.7.

The free ammonia during the year 1899 averaged 4.99, in the year 1900 it was 1.311.

Nitrogen as albuminoid ammonia, total, for 1899 the average was .498; for 1900, .39.

The albuminoid ammonia derived from dissolved substances was in 1899, .399; in 1900, it was .244.

8706 The albuminoid ammonia from suspended matters was in 1899, .0997; in 1900 it was .147.

The total organic nitrogen was in 1899, on the average 1.111; in 1900 it was .848.

The organic nitrogen in dissolved matters was during the year 1899, .824 and during 1900 was .537.

Organic nitrogen in suspended matters was in 1899, .287; in 1900, .311.

Nitrogen as nitrites in 1899 the average was .495; in 1900 it was .25.

The nitrates in 1899 were 1.857 and in 1900 were 1.62.

Q. I call your attention now to tables of this series numbered 24, 25, 26 and 27. Did you prepare any table of averages based upon the ascertainment contained in these tables, which were the chemical examinations of water in the Illinois river at LaSalle?

A. I did.

Q. Have you that table with you?

A. I have. It is table of averages No. 7 A. W. P. and is as follows:

8707

DEFENDANTS' TABLE OF AVERAGES NO. 7.—A. W. P.

8708 Q. State what significance you attribute to these detail tables and this table of averages as to the waters at this point?

A. Tables 24, 25, 26 and 27 contain the data of all analyses of samples of water taken from the Illinois river at LaSalle during the years 1897 to 1900 inclusive. The yearly averages which appear at the bottom of these tables and averages for the year

1896 taken from the preliminary report heretofore referred to and introduced in evidence as defendants' Exhibit A for identification, are brought together in tables of averages No. 7 A. W. P. The samples of water taken at LaSalle were collected beside the wagon bridge at a point three miles below the mouth of the Big Vermillion river, but above the point at which most of the sewage of LaSalle and the final discharge from the Illinois and Michigan canal enter the river.

Between Ottawa and LaSalle the conditons in the river are such as favor the abundant growth of vegetation and the waters at this point consequently become charged with organic matters to a greater extent than at Ottawa. The nitrates also are found at this point in greater proportion than they are found at
8709 Ottawa, and they have not been very notably reduced in
proportion by the dilution resulting from the discharge through the Chicago main drainage channel, a fact which is noted from comparison of the averages for the four years preceding, and those for the year following the opening of the drainage channel.

From Lockport to Ottawa the mixing of the waters seems to be at no point complete, and variations in the analyses due to this imperfect mixing are frequent, but a study of the conditions at LaSalle including analyses of cross-section samples has shown that at this point the waters have ordinarily mingled completely. Just below the town of LaSalle there occurs the final discharge from the Illinois and Michigan Canal which carries most of the sewage of LaSalle and the discharges of sewage and manufacturnig wastes from the town of Peru. It should be noted at several points between Joliet and LaSalle there are minor discharges from the Illinois and Michigan Canal into the Desplaines river and the Illinois river, and that prior to the opening of the drainage channel the old canal, that is, the Illinois and Michigan canal, at times carried practically undiluted Chicago sewage throughout much of the sixty-six miles of its lower course. Indeed, in period of low water, the channel often carried the entire body of Chicago sewage past Joliet and dis-
8710 charged it at various points many miles below that at
which it is now delivered into the river, thus carrying the pollution much farther down stream than the points at which it is now found.

Since the opening of the main drainage channel the diluted sewage which enters the stream between Lockport and Joliet is mainly carried by the Desplaines and Illinois rivers, and the volume discharged from the canal at points below Joliet constitutes a much smaller proportion of the volume of the river. Moreover, the water of the channel is now in far better condition because of its great initial dilution at Joliet and the more thorough-going natural purification thereby occasioned.

Comparison of the averages for the year 1900 with the composite averages for the four preceding years show that the water of the Illinois river at LaSalle contained less than two-thirds as much chlorine. in the year 1900 as it did on the average fo: the four preceding years, the figures being 18.7 for 1900 and 30.28 for the four preceding years; while the averages for the year 1899 was 44.7.

The oxygen consumed for the year 1900 was 10.1, while the average for the four preceding years was 12.55, and for the year 1899 was 13.6.

Oxygen consumed by dissolved substances was 7.2 for 1900 as against 9.36 for the four preceding years, and 10.4 for the year 1899.

8711 The oxygen consumed by suspended matters was 2.9 in 1900 as against 3.19 as the average for the four preceding years, or 3.2 the average for the year 1899.

The nitrogen as free ammonia, was an average, .963 for the year 1900 as against 1.658 the average for the four preceding years, and 2.536 the average for the year 1899.

The albuminoid nitrogen, total, for 1900 was on the average .391, while for the four preceding years it was .5455.

Albuminoid ammonia derived from dissolved substances was for 1900, .251; for the four preceding years it averaged .387.

Albuminoid ammonia derived from suspended matters was for 1900, .141; for the four preceding years it was .158.

Total organic nitrogen for the year 1900 was .944, the average for the four preceding years being 1.234.

The organic nitrogen in dissolved matters was for 1900, .611; for the four preceding years the average was .852.

Organic nitrogen in suspended matters for the year 1900, was .333; for the four preceding years the average was .386, and for the year 1899 the average was .478.

Nitrogen as nitrites, the average proportion for the year 1900 was .152; while for the four preceding years it was 8712 .333.

Nitrogen as nitrates, the average for the year 1900 was 1.7, the average for the four preceding years being 1.89.

It is evident from the comparison of these averages that the proportions of organic matters contained in the waters of the Illinois river at LaSalle have been very considerably reduced as a result of the greater dilution produced by the opening of the Chicago main drainage channel, that the proportions of nitrogen as nitrites is now less than one-half what it was before the opening of the drainage channel, while the proportions of nitrogen as nitrates are but slightly less than they were before that opening.

Q. I will now call your attention professor, to tables in this series numbered 28 to 32 inclusive, which contain the chemical examinations of water from the Illinois river at Averyville. Please state whether you prepared any table of averages based upon these tables?

A. I did prepare such table of averages.

Q. Have you that table with you?

A. I have. It is Defendants' table of averages No. 8, A. W. P. and is as follows:

8713

DEFENDANTS' TABLE OF AVERAGES NO. 8.—A. W. P.

TABLE XII.

CHEMICAL EXAMINATION OF THE WATERS OF THE ILLINOIS RIVER AT AVERYVILLE. YEARLY AVERAGES. PARTS PER MILLION.

8714 Q. Now what significance do you attach to these tables and to the table of averages which you have just put in evidence?

A. The tables Nos. 28 to 32 inclusive contain the data of analyses of samples of water taken from the Illinois river at North Peoria or Averyville. That is beside the bridge at the Narrows, three miles above the Peoria Court House, a point where none of the sewage of Peoria finds its way into the waters of the stream.

The analyses were made upon samples which were collected regularly each week throughout the period in question beginning April 26, 1897, and ceasing December 26, 1901, except that during the first half of the year 1901 the collections were made but once a month, the averages however, for such years as are not covered by regular weekly samples have been made first for each month in the year, and the year's average made up from the monthly average. In other cases the averages have been made straight from the various weekly samples.

Between LaSalle and Averyville there is no considerable additional dilution of the waters of the stream and no great amount of impurites introduced except that discharged from the Illinois and Michigan canal just below LaSalle, which discharge contains most of the sewage of LaSalle, and in addition
8715 the discharge of the sewage and manufacturing wastes of Peru, which is just below LaSalle.

The study of the data of the analyses and particularly comparison with those for the other points along the river between Averyville and Lockport show unmistakably that a very great purification of the waters of the stream takes place as they flow along the 125 miles of its course between these two points. The seasonal variations in the water of the river at Averyville as may be seen by study of the detail analyses contained in tables 28 to 32 inclusive, are quite considerable, but the limits of variations are in most respects considerably less since the opening of the Chicago main drainage canal than they were formerly. The variations of the chlorine are shown diagramatically upon plate VIII.

It is quite natural under the existing circumstances, that the proportions of chlorine should be smaller during the high water period, that is, in February, March and April, and that in

the later season of the year, the warmer summer months, when the flow is very much reduced, the contents of chlorine should be much greater than at other periods, and this plate too, shows in general the difference between the first six months and the second six months of the year, for formerly, that is particularly before the opening of the Chicago main drainage
8716 channel there was a much more considerable difference
between high water conditions and low water conditions in the Illinois river with respect to the chlorine contained, as also with respect to the organic matters than is the case since the opening of the main drainage channel.

Plates IX and X show graphically the seasonal variations in content of free ammonia. Plate IX having upon it the data for the weekly analyses represented by curves for the years 1897, 1898, 1899 and 1900, while upon plate X the monthly averages, showing the proportions of nitrogen as free ammonia for the years 1897 to 1901 inclusive are represented.

The curves of both of these plates show the general variations in the content of nitrogen as free ammonia, as it varies with the seasons, the proportion being very great in the cold weather season, that is in January and February, and in general too, in November and December, while the proportions during the warmer seasons, that is the late spring, the summer and the early autumn seasons, are very much less than at other times during the year.

It is very noticeable that both before and since the opening of the Chicago main drainage channel the proportions of free ammonia are much greater in cold weather than at other seasons, and it is evident too, that the proportions of free
8717 ammonia content in the water of the Illinois river at
Averyville are much less since the opening of the Chicago main drainage channel than they were before that time.

Plate XI of this series gives by means of curves the proportions of nitrogen as nitrites contained in the water of the Illinois river at Averyville, these being represented as monthly averages.

The curves of this plate show at a glance that the period when nitrites are most abundant in the Illinois river water at Averyville, is in general the summer time, or early autumn, when the flow is at the minimum and the temperature at the maximum. The conditions with respect to nitrates being just the opposite to those referred to above, with respect to the nitrogen as free ammonia. It is evident from the figures in tables of analyses, and it is shown graphically upon the plate, that the proportions of nitrites since the opening of the drainage channel are in general less throughout the year than they were before the opening of the main drainage channel.

Comparison of the figures of table of averages No. 8, show that as a result of the dilution effected by the opening of the Chicago main drainage channel, or at least subsequent to that opening, the proportions of the various significant constituents of the water of the Illinois river at Averyville are very
8718 greatly reduced.

The data throughout show this. The chlorine has been reduced from 20.2 the average for the three years prior to the opening of the drainage channel, to 17.5, the average for the two years subsequent to the opening. Similar reductions in the proportions of oxygen consumed both the total and that consumed by dissolved and by suspended matters, are evident. That the nitrogenous organic matters are very much reduced in proportion is evidenced at once by comparison of the relative quantities of nitrogen as albuminoid ammonia, and the total organic nitrogen for the two periods, the total organic nitrogen being on the average for the two years of 1900 and 1901 .742, while the average for the three years 1897 to 1899, is .98.

The total organic nitrogen in dissolved matters being .555 for the two years 1900 and 1901 as against .72 for the three years prior thereto. The nitrogen in suspended matters for the two years 1900 and 1901 being .187 as against .262 the average for the three preceding years.

The nitrogen as albuminoid ammonia, the total, was for the years 1900 and 1901 .286, while for the three years preceding the average was .466.

The albuminoid ammonia derived from dissolved sub-
8719 stances being for the years 1900 and 1901 .212, while for
the three years preceding, it was .336.

The albuminoid ammonia derived from suspended matters was on the average for the years 1900 and 1901 .076, and for the three preceding years the average was .13.

The proportion of nitrogen as free ammonia for the years 1900 and 1901 was .643, while for the four preceding years the proportion was .909, and for the year 1899 the proportion was 1.025.

The proportion of nitrogen as free ammonia thus was less than two-thirds as much in the waters of the Illinois river at this point after the opening of the Chicago main drainage channel than it was prior thereto.

Comparison of the proportions of nitrites shows a very great decrease at this point since the opening of the drainage channel, the quantity being less than one-half that formerly contained. Thus the proportions of nitrogen as nitrites on the average for the years 1900 was .079, for the year 1901, .081, and the average for the two years being .08.

The average proportion of nitrogen as nitrites for the year 1897 was .254; for the year 1898 .124; for the year 1899, .204; the average for the three years being .194, considerably more than twice the proportion found in the water at this point since the opening of the drainage canal.

8720 That the reduction of these constituents is not wholly due to mere dilution, but that in part at least it is due to the greater proportional destruction of the organic matters discharged into the stream at Lockport and Joliet would seem to be evident from the fact that the nitrates are found in greater proportions in the water at this point now than they were before the opening of the drainage channel; the average proportion for the three years prior to the opening of the Chicago main drainage channel being 1.351 while the average for the two years subsequent to the opening of the channel was 1.46.

Comparison of the figures of table 8 for Averyville, with those of table 7 for LaSalle, show that there has been a very great decrease in the organic matters during the flow of 60 miles between these two points. The diminution is very considerable in each case, even including the nitrates, but the most significance attaches to the marked diminution in the proportions of nitrites and free ammonia and albuminoid ammonia, and total organic nitrogen. The proportions of nitrites have been reduced about fifty per cent., which would appear to indicate that the nitrification processes are approaching completion; this in turn

indicating that those organic substances which are easily
8721 susceptible to bacterial action have in great part already
been consumed. In fact, it is highly probable that the refuse animal matters introduced in the sewage of Chicago have been completely destroyed, and that the organic matters which are contained in the river water at this point are derived from vegetable and not from animal sources.

MR. JEFFRIES: I move to strike out what the witness says is highly probable, as not having a reasonable foundation upon which to base it.

A. (Continuing) In fact, vegetation of various forms, the plankton, and so on, is exceedingly abundant in the river between LaSalle and Averyville. The water of the river between these points and especially near Averyville may often be seen covered with floating masses of vegetation consisting largely of filamentis and other algae.

Comparison of the averages for Averyville with those for the tributary streams serves to show that the waters of the Illinois river at this point contain considerably less organic matters than are contained in the waters of its chief tributaries, which latter have never been in contact with Chicago sewage, although of course they receive some sewage from comparatively small towns. It is very evident of course that free ammonia and nitrites are still present in the waters of the Illinois river at this point in greater quantities than are
8722 contained in most of the tributary streams but the considerations detailed above and all available data show unmistakably that the character of the water in the streams at Averyville is now far better than it was before the Chicago sewage received its initial dilution at Chicago, and not at the junction of the Desplaines and Kankakee rivers, sixty miles nearer to the point now under consideration.

JUDGE SPRINGER: Q. Professor, you used the words "Highly probable" in reference to the destruction of the sewage matter which has been introduced into the Illinois river from the Chicago drainage canal. State what your opinion is upon that fact.

MR. JEFFRIES: I object to the witness expressing an opinion on the subject for the reason that he is not a sanitarian and has not qualified as such, and for the further reason that the defendants have prided themselves on the proposition that chemistry is an exact science, and therefore if it is an exact science nothing can be probable, but must be certain.

Q. (Question read.)

A. It is my opinion that the animal matters discharged by the two canals, the Chicago main drainage channel and the Illinois and Michigan canal, into the Desplaines river in the vicinity of Lockport and Joliet, and discharged by the Desplaines 8723 into the Illinois river about ten miles above Morris, have been entirely destroyed before the waters of the Illinois river reach Averyville, and the substances of said animal matters have been in part converted into mineral substances, and in part built up into the substance of living vegetation, this opinion being based upon my study of the waters of the streams in question, at the various points enumerated in my testimony in this case, and upon the evidence of the chemical analyses which have been introduced as part of my testimony.

Q. I now call your attention, Professor, to the tables in this series numbered 33, 34, 35 and 36, which contain the chemical examinations of water from the Illinois river at Havana. Have you prepared a table of averages based upon those detail examinations?

A. I have, and it is Defendants' Table of Averages No. 9, A. W. P., and is as follows:

8724

DEFENDANTS' TABLE OF AVERAGES NO. 9.—A. W. P.

TABLE XIII.

CHEMICAL EXAMINATION OF THE WATERS OF THE ILLINOIS RIVER AT HAVANA.
YEARLY AVERAGES: PARTS PER MILLION.

Year	Chlorine	OXYGEN CONSUMED.			NITROGEN AS AMMONIA.				ORGANIC NITROGEN.			NITROGEN AS

8725 Q. State what conclusions you have drawn from an examination of these detail examinations and the tables of averages which you have just put in evidence?

A. Tables 33 to 36, inclusive, give the results of analyses of samples collected during the years 1897 to 1900, inclusive. The yearly averages which appear at the bottom of these tables have been brought together in table of averages No. 9, and together with them there has been included in table No. 9, the year's averages for the year 1896, the details for which appear in the preliminary report several times heretofore referred to as Defendants' Exhibit A for identification.

The collections for Havana were made at a point about a mile and a half above the town, above the mouth of the Spoon river and the mouth of Quiver Lake, between Averyville and Havana. The sewage and manufacturing wastes are introduced into the river at Peoria and Pekin in quantities second only to those introduced through the Chicago main drainage channel and the Illinois and Michigan canal. These, however, consist very largely of refuse from stockyards, from cattle sheds; from some 40,000 to 50,000 cattle which are fed upon distillery slops, and the wastes from large glucose works, and other manufacturing industries.

Prior to the opening of the Chicago drainage channel—

8726 MR. JEFFRIES: Is that per annum—40,000 to 50,000 head per annum?

A. Why, continuously. I don't understand exactly what you mean,—per annum.

MR. JEFFRIES: The cattle that are fed at Peoria during the year?

A. No, during the year; they are constantly fed—there are constantly that number fed there.

8727 Prior to the opening of the Chicago draïnage canal the condition of the river along this stretch of 45 miles was at many places during the summer time practically that of an immense septic tank. The offensive condition of which was striking throughout much of this stretch, but was greatest in the near vicinity of Peoria and Pekin.

The data of the detailed analyses which appear in the tables 33 to 36, inclusive, show the seasonable variations similar to those which were found at Averyvile in comparison of the yearly averages which are brought together in table of averages No. 9, A. W. P., with those for Averyville which appear in table of Averages No. 8, A. W. P., show that notwithstanding the introduction of an enormous amount of filth between Averyville and Havana, the putrefactive and other purifying processes going on in the waters of the stream have sufficiently reduced them to proportions of the various constituents so much that they were but slightly different at Havana from what they were at Averyville, although an analysis of samples taken at Wesley just below Peoria and also at Pekin, show a notable increase in the content of organic matters at these two points, above the quantities found at Averyville and above those found at Havana, thirty miles below Pekin.

Comparison of the figures for the year 1900 with those of the years 1896 to 1899, inclusive, all of which appear in

8728 Table of averages No. 9, shows the effect of the opening of the Chicago main drainage channel in reducing the proportions of the various constituents here considered. With the exception of the nitrates, the reduction of the various constituents is very considerable. The fact that the nitrates are not proportionally lowered seems to indicate that oxidation at this point is more complete since the opening of the sanitary canal than it was previously.

Numerous determinations of dissolved oxygen in the waters of the Illinois river at Havana covering several years show that although at times the water is saturated in general, the content of dissolved oxygen is at this point considerably less than is required for saturation and at all times the dissolved oxygen diminished rapidly upon allowing samples to stand, as will be shown hereafter when a table upon that subject will be presented.

Q. I now call your attention to tables in this series Nos. 37, 38, 39, 40, 41, 42 and 43, which contain detailed chemical examinations of the water taken from the Illinois river at Kampsville, will you please state whether you prepared the table of averages based upon these tables?

A. I did.

8729 Q. Will you produce it, please?

A. It is Defendants' Table of Averages No. 10, A. W. P., and is as follows:

8730

DEFENDANTS' TABLE OF AVERAGES NO. 10.—A. W. P.

TABLE XV.

CHEMICAL EXAMINATION OF THE WATERS OF THE ILLINOIS RIVER AT KAMPSVILLE.

YEARLY AVERAGES. PARTS PER MILLION.

8731 Q. What conclusions have you drawn in reference to these tables as exhibited therein. I mean the table of averages just presented ?

A. The tables numbered 37, 38, 39, 40, 41 and 42, Department of Chemistry, University of Illinois, A. W. P., give details of the analyses of samples of water collected from the Illinois river at Kampsville a few hundred feet above Kampsville Dam, during the years 1897 to 1902, inclusive, the samples being collected regularly once each week throughout this period of six years, three years prior to the opening of the Chicago main drainage channel and three years subsequent to the opening of the Chicago main drainage channel. The comparison of the data of the two three-year periods affords an excellent opportunity of judging of the effects of dilution occasioned by the opening of the Chicago main drainage channel upon the character of the waters of the Illinois river as they are about to flow into the Mississippi river at Grafton thirty miles below Kampsville.

We will consider first some of the data as represented graphically upon plates and then discuss the general averages which appear in table No. 10.

Plates Nos. XII and XIII show that in the usual high water period, that is, the first half of the year, chlorine is contained in the water of the Illinois river at this point in 8732 just as considerable proportions as before the opening of the Chicago main drainage channel but that in the latter part of the year which was formerly a period of extremely low water, the content of chlorine is now found to be considerably less than formerly, the seasonal variations as revealed by regular weekly analyses being represented upon plate XII by lines for the years 1897 to 1900, inclusive, and upon plate XIII, the averages for each month being represented for the years 1897 to 1901, inclusive.

Plate No. XIV represents variations in the proportions of nitrogen as free ammonia, and shows the great difference in respect to proportional content of free ammonia between cold weather and warm weather conditions.

Plate XV represents the seasonal variations in the proportions of nitrogen as nitrites and shows that the nitrites are not contained in the river at this point in so great quantity as they were previous to the opening of the Chicago main drainage channel, but that they follow the same general course of seasonal variations as formerly; that is, they are least in cold weather and greatest in hot weather.

Plate XVI shows by means of monthly averages, the proportions of total organic nitrogen both dissolved and total
8733 and the seasonal variations which took place with respect
to the content of nitrogenous organic matters.

Comparison of the averages for the three years 1897, 1898 and 1899 with each other shows no very great variation in the organic matters, though the oxygen consumed, the free ammonia and the total organic nitrogen increase somewhat from year to year, while the nitrites and the nitrates decrease.

Comparison of the averages for 1900 with those for 1899 show that immediately after the opening of the Chicago drainage channel there was a notable decrease in the proportions of the various constituents with the single exception of nitrates. The decided increase of which, taken into consideration with the 25 per cent. decrease in the proportion of nitrogen as albuminoid ammonia indicates that under the new conditions the oxidation of the organic matters is more complete as the waters of the Illinois flow along its course from the point of initial pollution by Chicago sewage to Kampsville where they are about to discharge into the Mississippi river, that is, within 30 miles of the point at which that discharge into the Mississippi occurs.

The averages for 1901 correspond fairly well with those for 1900 except that the total organic nitrogen appears decidedly higher, but this is due to the fact that the data for this constituent cover but the first nine months of the year
8734 as a press of overwork made it necessary to discontinue
the determination of total organic nitrogen at this time. The higher free ammonia in 1902 over the proportions contained in 1901 and 1900 is chiefly due to the fact that in January and February, when the cold weather conditions are usually accompanied by high free ammonia in the Illinois river, the stage of water in the Illinois was remarkably low and the concentration correspondingly great.

Comparison of the averages for the two 3-year periods makes evident the great diminution in the proportions of the various constituents except free ammonia which is .393 parts per million in the latter period as against .371 parts per million in the earlier period and the nitrates, which have very considerably increased.

Plate XVII exhibits graphically by means of columns some of the facts shown in table of averages No. 10 and facilitates the comparisons between the averages for the separate years.

It is hereby agreed between counsel on both sides that the samples of water taken from the upper Kankakee river near South Bend, Indiana, by George W. Van Schotten, as stated by Professor Long in his testimony, were taken in the manner described by Professor Long as near as may be, and that the
8735 sample of water taken from the upper Desplaines river
near Libertyville by Mr. Clare Sherman were taken as stated by Professor Long in his testimony and in the manner therein stated as near as may be, and that the samples of water taken from the upper Fox river at McHenry as shown by the testimony of Professor Long were taken by Mr. Charles F. Fegers in the manner described by Professor Long as near as may be, and that the samples of water taken from the Mackinaw river at Kappa and analyzed and used by Professor Long in his testimony were taken by Dr. R. E. McKenzie in the manner described by Professor Long as near as may be, and that the samples of water taken from the upper Sangamon at Mahomet by Dr. John H. Gardiner, were taken in the manner described by Professor Long, as near as may be, and that the production of said witnesses is hereby waived. These facts are to be considered in evidence the same as though said persons had been sworn and their testimony produced in evidence, subject to the objections of the complainant in this, to wit, that the taking of samples of water and analyses of these samples from the tributaries of the Illinois river, is incompetent, irrelevant and immateial and has no bearing upon the issues involved in this case.

Adjourned until 10:00 a. m., following day, Tuesday, November 17, 1903.

10:00 A. M., Tuesday, November 17th, 1903.

8736 Continuation pursuant to adjournment.

Present, the Commissioner and same counsel representing the respective parties.

PROF. ARTHUR W. PALMER,

resumed the stand for further direct-examination by Judge Springer and testified as follows:

JUDGE SPRINGER: Before proceeding with the examination of Professor Palmer, I desire to present a table representing the dissolved oxygen in the Illinois river at Havana. This may be considered as offered for identification, and is entitled "Department of Chemistry, University of Illinois, Defendants' Exhibit B for identification,—A. W. P."

MR. JEFFRIES: Professor, I understood you to say yesterday that this did not comprise the dissolved oxygen for all the samples that were taken by you at this place,—or examined by you at this place?

A. All that were examined for dissolved oxygen except one or two samples that were taken subsequently, but practically all, yes.

Q. Yes, but does it embody the results for dissolved
8737 oxygen of all samples that were chemically analyzed and
taken from this place at Havana?

A. Yes, during the length of time covered by the dates there it does.

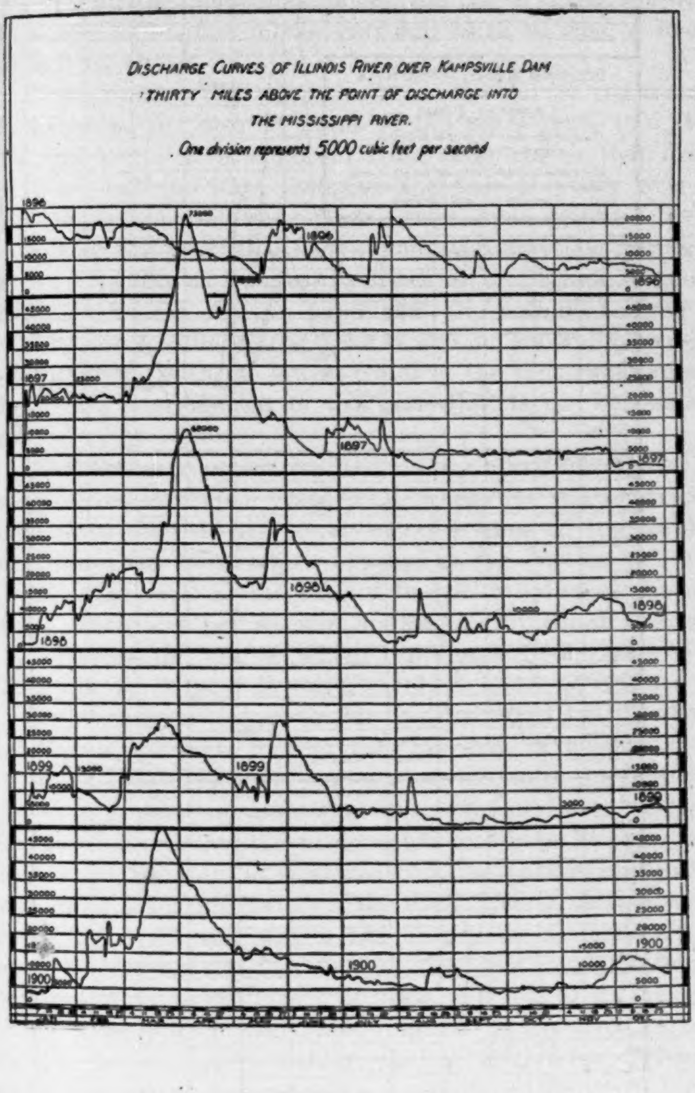
MR. JEFFRIES: I object to the exhibit being introduced for identification for the reason that it relates to a period of time prior to the opening of the Chicago drainage canal and is therefore irrelevant and immaterial.

JUDGE SPRINGER: Professor, will you proceed with your explanation of the chemical examinations of water at Kampsville and table of averages based thereon?

A. With respect to the higher proportion of free ammonia in the water during the second period of three years, that is the period subsequent to the opening of the Chicago Drainage channel it is evident that this is mainly due to the unusually high proportion of free ammonia contained in the water of the stream at this point during the year 1902. The proportions of free ammonia during the months of January and February, 1902, were particularly excessive; the weather being at this time very cold and the volume of water in the stream being unusually small, even for this season of the year, and the proportion,—that is the average proportion for the year is at a higher point for the reason that the year 1902 was on the whole an unusually high water year. The water was 8737a higher, particularly during the ten months following February, than it had been at any time during the six years here under consideration.

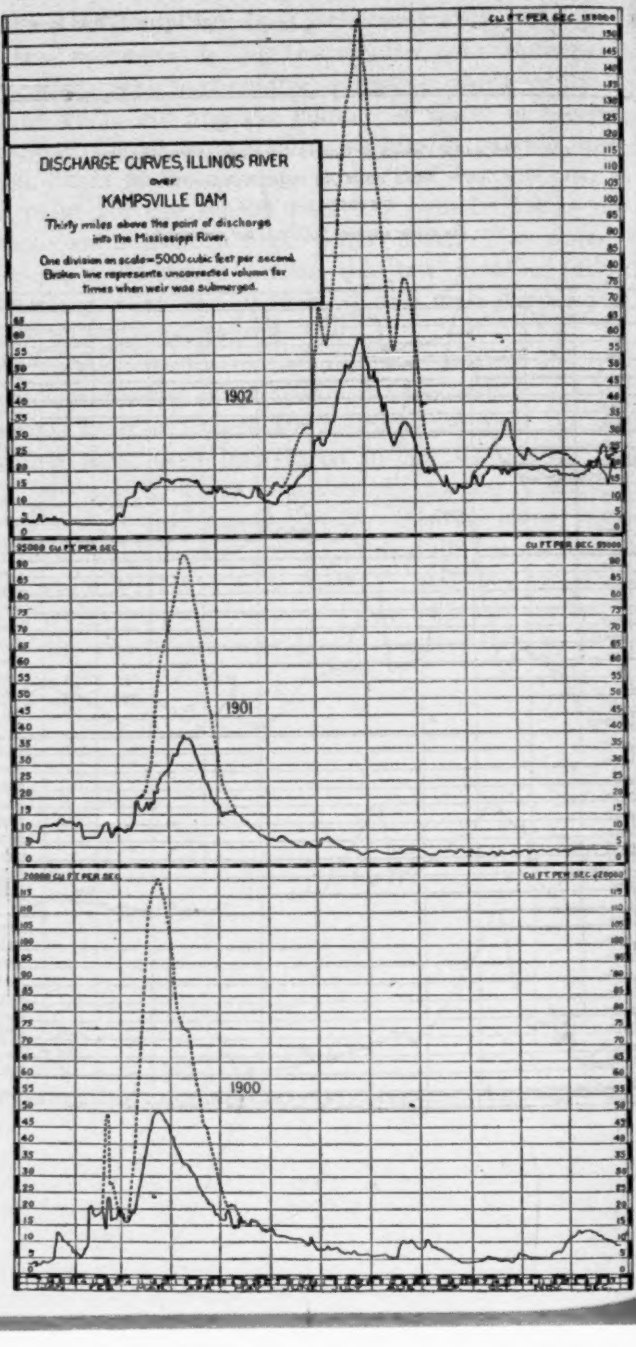
As bearing upon this matter and as a basis for the realization of the significance of the seasonal variations in the waters of the Illinois river at Kampsville as indicated upon the several plates which have been introduced in my testimony, I have prepared two plates, which represent by means of curves the volume of water discharged by the Illinois river over the Kampsville dam during the years 1896 to 1902 inclusive. These are plates Nos. XVIII and XIX, A. W. P., and they are prepared from data which give the mean flow per 24 hours for each day of each of the years here considered, namely, 1896 to 1902, inclusive, and are as follows:

Plate XVIII.—A. W. P.



DISCHARGE CURVES OF ILLINOIS RIVER OVER KAMPSVILLE DAM THIRTY MILES ABOVE THE POINT OF DISCHARGE INTO THE MISSISSIPPI RIVER.

One division represents 5000 cubic feet per second



DISCHARGE CURVES, ILLINOIS RIVER
over
KAMPSVILLE DAM

Thirty miles above the point of discharge into the Mississippi River.

One division on scale=5000 cubic feet per second. Broken line represents uncorrected volume for times when weir was submerged.

Plate XIX.—A. W. P.

8740 Inspection of the plates and comparison of the curve representing conditions in the year 1902 with the curves representing the conditions during the other years, shows the differences as to time in the year and as to volume of flow as referred to above.

Upon Plate XVIII there is shown the curves representing the discharge for each 24 hours of the years 1896, 1897, 1898, 1899 and 1900. It is apparent from these curves that during the years 1897 to 1900, inclusive the flow of water over the Kampsville dam followed much the same general course throughout the year; that is, was comparatively low during the first two months of the year and was at its highest in general in March, and in April. After that the volume became less until by the middle of the year it had in general reached an ordinary stage with the lowest water of the year coming generally in the later months of the year, that is the late summer and the early atumn.

The curves representing the flows during the years 1901 and 1902, appear upon plate XIX, where for the purposes of comparison there is also given at the bottom of the plate the same curve for 1900, which appears at the bottom of plate XVIII. The scale at the side of the plate indicates the number of cubic feet per second, and the point where the curve crosses the line to which the figure in the scale at the
8741 side pertains, indicates the volume of water passing over the dam on the particular day indicated by the vertical line, which intersects the curve to the scale or horizontal line.

Upon plate XIX there is given in addition to the continuous curved line showing the actual flows of water, also a broken line which represents the uncorrected discharge at times when the wier at Kampsville is submerged, the submergence of the weir takes place generally in the early spring or late winter, that is, in April and March, but during the year 1902 it did not occur during the first half of the year, but submergence first took place in the month of June, and was at its maximum in the latter part of July and August. It occurred again in the late fall and early winter; that is in October, November and a portion of December.

The data represented by the continuous lines represent the volumes of discharge computed by wier formula, corrected for submergence of wier; the broken lines represent the volume calculated by wier formula, without correction for submergence of the wier and of course they are far in excess of the actual discharge of water.

Q. Can you explain that wier formula for measuring the water?

A. What do you mean? Tell what a wier is, or—

Q. Yes, what it is?

A. By wier here we mean simply the dam itself, or the
8742 crest of the dam, the particular portion of the dam over
which the water finally passes in its passage from the stretch of river above the dam to the stretch immediately below the dam.

Q. Have you prepared any data in regard to this point that you have not heretofore put in evidence?

A. As I have just stated, the data giving the discharges for each 24 hours of the six years under consideration, are here for introduction.

Q. What was the basis upon which these data were prepared?

A. The United States Engineer who is in charge of improvements along the lower Illinois river, and in residence at Kampsville Dam, which is a part of the government property in his charge, makes readings of the height of water above and below the Kampsville dam three times every 24 hours. These data are published in the reports of the Chief Engineer of the United States Army, and have also been furnished to me privately by the engineer in charge of the work, this latter appertaining particularly to such of the data as have not yet been included in government reports, for government reports frequently are slow in going through the press.

The data covering the volume of discharge have been calculated as above indicated, by use of the wier formula from the
heights of water above and below the dam, as recorded
8743 by the government engineer.

JUDGE SPRINGER: I now offer these tables of discharges in cubic feet per second of water over the Kampsville dam, for the years indicated on each of these plates—

MR. JEFFRIES: Set out the years Judge.

JUDGE SPRINGER: What are the years? You had better identfy them.

A. Years 1896, 1897, 1898, 1899, 1900, 1901 and 1902.

JUDGE SPRINGER: I now offer these tables in evidence. They will be numbered from 1 to 7 A. W. P.—Tables of Discharges of water over the Kampsville dam in cubic feet per second for the years 1896 to 1902 inclusive. The tables are as follows:

8744

Discharge over Kampsville Dam For the Year 1896.

Number of Cubic Feet per Second.

Day	January.			February.			March.			April.		
	H.	H/H	Q	H	H/H	Q	H	H/H	Q	H	H/H	Q

8765 Q. Now professor, will you explain in detail the tables which have just been put in evidence, and show what relation they have to other data put in evidence in this case by yourself?

A. With respect to table No. 1 of this series, I may say that the first column gives the date of the month, the day of January for instance, beginning with January, 1896. In the second column we have under the letter "H", the height of water above the wier, taking the first figure, it represents the fact that the height of water above the crest of the dam or wier was 3.68 feet. The height of water above the wier, but below the wier,—that is vertical height, above the wier, but measured at a point down stream from the wier, is not given in this table, but the percentage calculated by dividing the one height by the other is given in column 3. This gives the coefficient by which the flow—the actual discharge of water over the wier is to be computed by multiplication into the figure showing the volume of discharge which would have occurred if the height of water down stream from the wier was not higher in the vertical line than the crest of the wier itself. The figures in column four marked "Q" represent the number of cubic feet per second of water discharged over the dam.

The same explanation appertains to the various other columns of figures for this table and also for the other seven of this set.

8766 Q. I understand you to say professor, that these tables were the basis upon which the charts or plates were made?

A. They are.

Q. Professor, I now call your attention to tables 43, 44, 45 and 46 of the series under consideration at the time of adjournment yesterday, containing the chemical examination of water from the Illinois river at Grafton, covering the periods designated in the left hand margin of the tables. Will you please state whether you prepared a table of averages based upon these detail examinations?

A. I did, and it is Defendants' Table of Averages No. 11—A. W. P. and is as follows:

8767

DEFENDANTS' TABLE OF AVERAGES NO. 11.—A. W. P.

TABLE *XVI.*

CHEMICAL EXAMINATIONS OF THE WATERS OF THE ILLINOIS RIVER AND THE MISSISSIPPI RIVER AT GRAFTON, BEFORE AND AFTER THE OPENING OF THE CHICAGO MAIN DRAINAGE CHANNEL.

8768 Q. Now will you please state what significance you attach to these chemical examinations as illustrated by this and also by the table of averages which you have just put in evidence?

A. The samples of water, analyses of which are detailed in tables 43 to 46 inclusive, were collected from the Illinois river at a point about two miles within the mouth, a place which is not ordinarily reached by water from the Mississippi river. There are several islands in the Mississippi river close to the mouth of the Illinois, lying parallel with and at no great distance from the Illinois shore, and the United States engineers in charge of this section of the improvements of the Illinois and Mississippi rivers have had dikes built between these islands.

which prevent the waters of the Illinois from discharging into the Mississippi at its old mouth and cause them to pass down for at least two miles parallel with the Mississippi river before finally entering the latter immediately opposite the town of Grafton. In times of high water the discharge from the Illinois river flows over these dikes into the Mississippi at points between one and two miles above Grafton, and also at times the waters of the Mississippi flow over the dikes into the Mississippi.

8769 Our samples were collected above the point at which this occasional mixing takes place.

Comparison of the data of the analyses show seasonal variations of considerable magnitude in the waters of the Illinois river at Grafton, the most important of which the albuminoid ammonia and the total organic nitrogen are shown in plates XX and XXI, which are as follows:

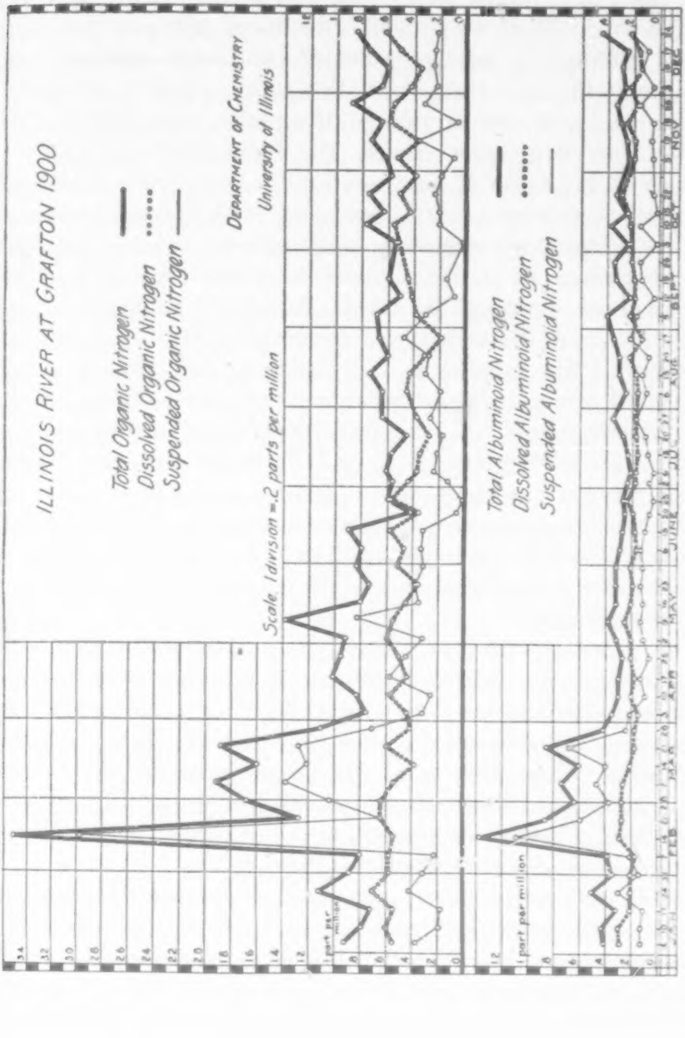
Plate XXI.—A. W. P.



8772 Upon plate XX there is shown by means of curves, the seasonal variations in the content of albuminoid nitrogen, both the total, that derived from dissolved substances, and that derived from suspended substances for each sample collected during the year in question, and by similar curves, similar data with respect to the total organic nitrogen, are shown in the upper section of the plate. Inspection of these curves serves to show clearly the facts which appear in the details of the table of analyses for the year 1899, that is table No. 3 of the series we are discussing, with respect to the nitrogen as albuminoid ammonia and the total organic nitrogen.

Beginning at the left hand side of the plate and following the line representing the total albuminoid nitrogen it is evident that from the last day of December, 1898 to the 5th day of January, 1899, there was a decrease in the proportion of albuminoid nitrogen, while following that to the 18th, there was an increase, which in turn was followed by a decrease in the proportion to January 25th, and February 1st, and February 22nd, after which there was a sudden increase to March 2nd, when the proportions of nitrogen as total albuminoid ammonia amounted to 1.26 parts per million, while it had been but little more than .3 parts per million upon the 22nd of February
8773 preceding.

After the 2nd of March, there was a further increase to the 8th, after which there was a gradual decrease to the 15th and again to the 24th of March, after which a much more considerable decrease took place, between the 23rd and the 29th of March. From this point on the proportions of nitrogen as total aluuminoid ammonia were considerably less than they had been during March, although there were increases and decreases at various times throughout the year.

Similar facts appear when we consider the lines representing the total organic nitrogen, that is there was a notable increase at about the middle of January, which was followed by a decrease in the latter part of January, remaining about stationary during the early part of February. It slightly decreased in the latter part of February, to be followed by an enormous increase between the 22nd of February and the 2nd of March, the curves throughout following substantially the same directions as those above stated, with respect to the total albuminoid nitrogen.

It is obvious from inspection of the curves and is shown definitely by the figures of the tables to which the curves give expression, that during the times when the albuminoid nitrogen and the total organic nitrogen are particularly ex-
8774 cessive in quantity, in the water of the Illinois river at
this point, it is mainly in suspended matters and not in the substances which are in solution, while during the periods of less flow, the organic nitrogen and the albuminoid nitrogen are general chiefly in substances which are in solution in the water, and not in the matters which are merely suspended.

Upon plate XXI, there are shown similar lines for the year 1900. The lines follow much the same general course throughout the year. They represent the various analyses, the details of which are given in table No. 44 of this series.

Study of the figures of the table and inspection of the curves of the plate show that during the year 1900 the variations in the proportions of nitrogen as albuminoid ammonia and of total organic nitrogen follow much the same curves as during the preceding year, that is the year 1899, thus there was during the early part of January a decrease in the proportions which was followed in the latter part of January by an increase, to be again followed by a decrease to the 31st of January, which decrease in the case of the total organic nitrogen continued to the 7th of February, after which there was an enormous increase to the 14th of February, which again was followed by a considerable decrease to the 21st of February, which however was followed by another though less con-
8775 siderable increase to the 28th of February, and on to the
7th of March, after which again a decrease occurred, followed by an increase to the 14th, after which the decrease which occurred again was more considerable, and from that time on to the end of the year the proportions never rose to such considerable amounts as during February and March, and the variations were much less considerable from week to week.

Again with respect to the curves of this plate it may be stated that during the time when the proportions of total organic nitrogen and of total albuminoid nitrogen are at the maximum, or at the higher points, it is mainly due to the excessive proportion of the nitrogen contained in susupended matters, that is the greater proportion of the total organic nitrogen, as also of the nitrogen as albuminoid ammonia is at such times contained in matters which are in suspension in the water and not in the substances which are in solution.

Comparison of the averages for the different years which appear in the table of averages No. 11, above referred to shows that subsequent to the opening of the Chicago main drainage channel, the proportions of the various significant constituents of the water of the Illinois river at Grafton, were in most cases considerably reduced, thus the chlorine was found on the average for the year 1899 to be present to the extent of 14.73 parts per million, while the average for the year 1900 was
8776 13.13 parts per million, and that for the year 1901 15.3
parts per million, for the year 1902, 9.35 parts per million, while the average for the three years subsequent to 1899, was 12.6.

The oxygen consumed for the year 1899 was 12.6 parts per million; that for 1900—10.2; for 1901—11.3; for 1902—11.6.

That required by dissolved substances was, for 1899, 8.3; for 1900—6. 7; for 1901—7.5; for 1902—8, and the average for the three years was 7.4.

That required by suspended matters was, for the year 1899-4.3; for the year 1900-3.5; for 1901-3.8; for 1902-2.6; the average for the three years being 3.3.

The free ammonia was found to the extent of .313 parts per million during the year 1899. It was changed to the amount of .343 parts per million in 1900, and was found in the proportion of .234 in 1901, and in the proportion of .379 during the year 1902; the average for the three years being .322.

Total albuminoid ammonia was for 1899,—.479; for 1900 it was .375; for 1901, it was .413; for 1902 it was .322, and the average for the three years was .37 as against .479 for the year 1899.

The nitrogen as albuminoid ammonia in dissolved matters was, during the year 1899 on the average, .247 parts per million; during 1900 it was .191; during 1901, it was .241;
8777 during 1902-.229.

The nitrogen as albuminoid ammonia derived from suspended matters was, for the year 1899, .232; for the year 1900-.184; for the year 1901-.172; for the year 1902, .093, the average for the three years being .149, as against .232 the average for the year 1899.

The total organic nitrogen was on the average for the year 1899-1.148; for the year 1900 it was .855; a very considerable reduction; for the year 1901 it is given in the table of averages as 1.029, but it is to be noted that these particular determinations were not made after the first of October, 1901, and that the average for the year then appears higher than it would have been if the determinations had been made throughout this year. No determinations of organic nitrogen were made in the year 1902.

MR. JEFFRIES: With that explanation of the witness with reference to 1901, the determinations not having been made throughout the entire year, I object to any testimony or any conclusions being drawn either from the tables themselves or from the tables of averages for the reason that data are insufficient, and any conclusions that might be drawn would be erroneous and of not value for the determination of the issues involved in this controversy.

8778 JUDGE SPRINGER: The objection goes only to the weight of this evidence and not to its competency. Of course it has no further weight than the data upon which it is based.

THE WITNESS: (Contnuing) The total organic nitrogen derived from dissolved substances was, for the year 1899, .596; for the year 1900-.472; and for such portion of the year 1901 as the data of table 45 covers, it was .553.

The organic nitrogen derived from suspended matters was for the year 1899-.552; for the year 1900 it was .413; for the year 1901, or such portion as the data of table 45 covers it was .476.

The nitrogen as nitrites was, for the year 1899-.045 parts per million; for the year 1900 it was .025, a little more than half what it had been for the year 1899. In 1901 it was .033, and for the year 1902 it was .032; the average for the three years subsequent to the opening of the Chicago main drainage channel being .03, or two-thirds the proportion found in the waters of the Illinois river at this point during the year 1899; that is the year immediately prior to the opening of the Chicago main drainage channel.

Nitrogen as nitrates was, for the year 1899-1.063; for the year 1900, it was 1.364; for the year 1901, it was 1.273 and for the year 1902 it was 1.074, the average for the three years
8779 being 1.237, a considerable increase over the proportions found during the year 1899.

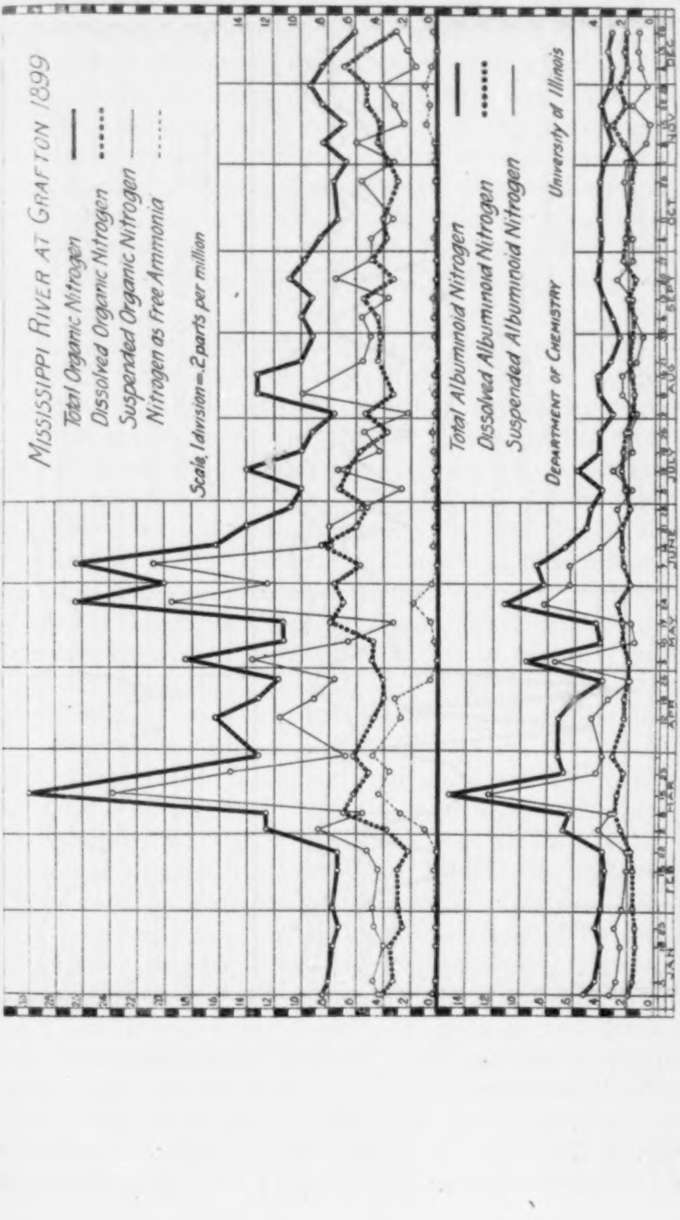
Q. Professor, I now call your attention to tables 47, 48, 49 and 50, of this series, which contain the chemical examinations of water from the Mississippi river at Grafton at the times indicated on these tables. Please state whether you prepared any tables of averages based upon these detail data and if so, will you please read the same into the evidence?

A. I did prepare such a table of averages from the data of tables 47, 48, 49 and 50, and will explain here that table 50 has not yet been printed, and that I put in evidence a manuscript copy of the table for the Mississippi river at Grafton, for the year 1902, the table of averages re-referred to is table No. 11, which we have been discussing for the Illinois River. This one table No. 11 contains not only the averages for the Illinois river, at Grafton, but also the averages of the analyses of samples taken from the Mississippi river at Grafton, those just referred to as being contained in detail in tables 47 to 50 inclusive.

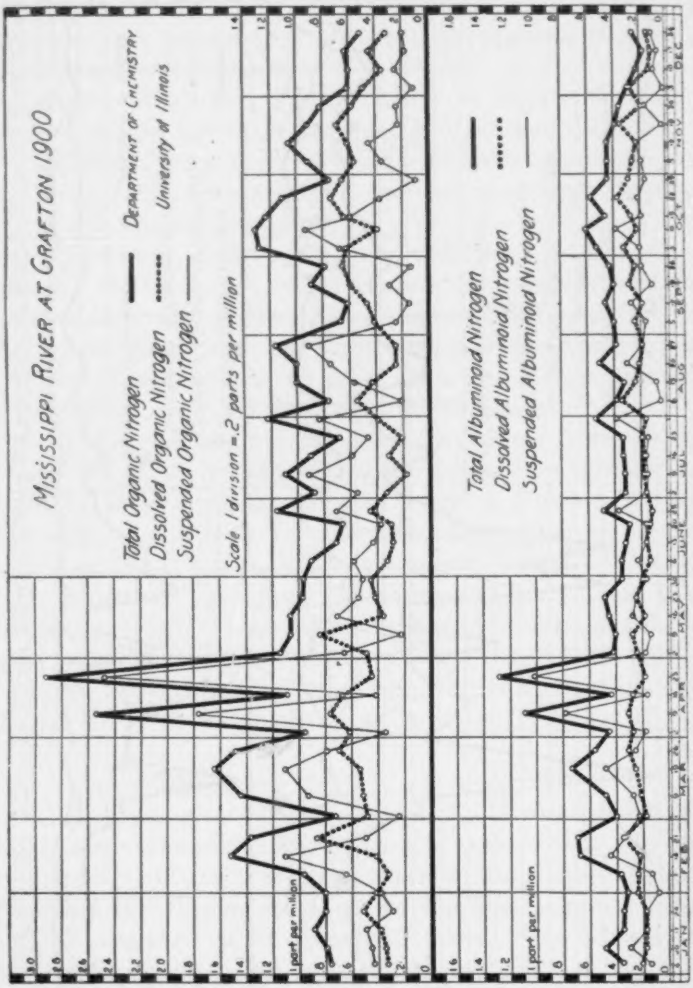
Q. Proceed, professor?

A. The samples of water from the Mississippi river at Grafton were taken at mid-stream, at a point about two miles above Grafton, and above that at which any discharge
8780 from the Illinois river enters the Mississippi. The detail analyses which appear in tables 47 to 50 inclusive, show that seasonal variations in the constituents of the waters of the Mississippi river are in many respects more frequent and more considerable than the seasonal variations in the waters of the Illinois. This is especially true of the albuminoid ammonia and the total organic nitrogen as is evident upon consideration of the features of plates XXII and XXIII, which are as follows:

Plate XXII.—A. W. P.



8782 **Plate XXIII.—A. W. P.**



Upon plate XXII there appear lines representing the 8783 total albuminoid nitrogen; the albuminoid nitrogen contained in dissolved substances, the albuminoid nitrogen contained in suspended substances. These being at the bottom of the plate, while upon the upper part of the plate there are shown lines representing the proportions of total organic nitrogen the organic nitrogen derived from dissolved substances, and that contained in suspended substances. In addition to these, there is a line representing the proportions of nitrogen as free ammonia, in the waters of the Mississippi river during the year 1899.

The plates are in all respects, so far as the scale and dates and general figurations are concerned, similar to tables XX and XXI, which have just been described, and which represent the proportions of these constituents, excepting the free ammonia, contained in the water of the Illinois river at Grafton.

With respect to plate No. XXII, we may follow the lines as we followed those of plates XX and XXI, and note that during the two months in the year 1899, the proportions of albuminoid nitrogen, and of total organic nitrogen vary but slightly, but that at the end of February there was an increase in some 8784 notable degree, which was followed in the early part of March by a slight decrease, this being in turn followed by a very considerable increase up to and upon the 15th of March, after which there was a decrease to the 23rd of March which in turn for the albuminoid nitrogen was followed by a slight increase to the 29th, while the total organic nitrogen decreased to the 29th. After this there was an increase in the total organic nitrogen to the 12th of April, to be followed by decreases until between the latter part of April and the 3rd of May there was again a considerable increase. The decrease which followed this being considerable, but being followed between the 17th and 24th of May by a very considerable increase. This followed by a decrease again to two parts per million, which was again followed by an increase to 2.6 parts per million, after which there was a very considerable decrease, but during the latter part of the year the proportions never rose to similar height to that reached in May, and in March. With respect to the free ammonia represented upon this plate,

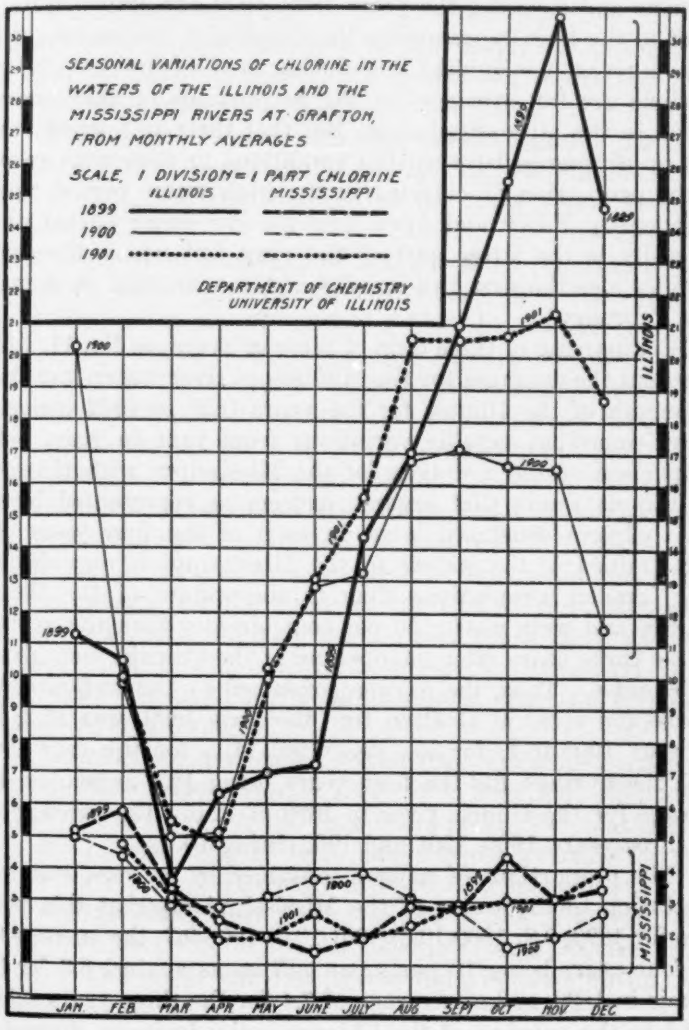
attention may be directed to the fact that the proportions in the water of the Mississippi river were extremely small for the first two months of this year, but that during March and April the proportions were quite considerable, reaching to more than four-tenths parts per million by the middle of March,
8785 and to nearly .5 parts per million at the end of March,
and that this considerable proportion of free ammonia persisted in the waters of the Mississippi until well along toward the latter part of April, after which there was a diminution and the proportions never again during the year reached quite the magnitude they reached during March and April.

In respect to plate No. XXIII in the consideration thereof, attention may be directed to the fact that in the early part of January, the proportions of total organic nitrogen were a little less than .8 parts per million, but there was a gradual increase to the middle of the month, followed by a decrease, but that in the early part of February there was an increase and up to the middle of February, 1900 the proportion of organic nitrogen contained in the waters of the Mississippi at Grafton were something more than 1.5 parts per million, the figure in the table being 1.52. After this there was a decrease in the proportion to the first of March, which was followed by a considerable increase again in March, reaching the maximum on the 19th and followed by a decrease in the early part of April, after which there were successive increases and decreases the maximum for the year being in the latter part of April, when the proportion of total organic nitrogen was found to be 2.92 parts per million. After this, the lines show various in-
8786 creases and decreases throughout the year, but at no
time during the latter part of the year was the proportion nearly so considerable as during the middle of February, the middle of March, and particularly the month of April.

The lines representing total albuminoid nitrogen follow practically the same course as that referred to with respect to the line representing total organic nitrogen and with respect to these two tables representing nitrogen as albuminoid ammonia and the total organic nitrogen in the waters of the Mississippi at Grafton for the years 1899 and 1900 respectively, it should be understood that the lines in the plates represent the figures which appear in detail in tables 47 and 48, and that during the times when the proportions of these constituents are at the maximum it is chiefly the suspended matters which contribute to the high proportion of the nitrogen.

Plate No. XXIV is as follows:

8787 Plate XXIV.—A. W. P.



8788 Upon Plate XXIV there appear lines which represent the proportions of chlorine contained in the waters of the Illinois river near the mouth at Grafton, and similar lines representing proportions of chlorine contained in the waters of the Mississippi at a point just above Grafton, the curves in this plate representing the monthly averages for the chlorine and covering the years 1899, 1900 and 1901. With respect to the lines representing the chlorine in the waters of the Illinois river, it is evident that during most of the year the proportions are far in excess of the proportions of chlorine contained in the Mississippi river, but that there is a great variation or difference between the conditions in this, with respect to the proportion of chlorine in the high water period, which is generally March and April, and the low water period which generally is the latter part of the year, but which frequently includes also the first two months of the year, that is, January and February.

Comparison of these data of table of averages No. 11, which represent the averages for the Mississippi river water just above the mouth of the Illinois for the years 1899 to 1902 inclusive, shows somewhat notable variations from year to year, but a comparison of the averages for the Mississippi with those for the Illinois shows that organic matters as represented by the

8789 oxygen consumed were, in each of the four years contained in the waters of the Mississippi in considerably greater proportions than in the waters of the Illinois in 1899, and were nearly 50 per cent. greater than the average for the three years after the opening of the Chicago main drainage channel. Thus, the oxygen consumed by the waters of the Mississippi river at Grafton for the year 1899, was 15.2; for the year 1900-16.4; for the year 1901-14.1; for the year 1902-14.7; the average for the four years being 15.1 as against the average for the Illinois river in 1899 of 12.6. The average for the three years, 1900, 1901 and 1902, being 10.

The proportions of oxygen consumed by matters contained in solution in the water of the Mississippi river at this point were for 1899, 9.8; 1900-10.6; 1901-10.6; 1902-9.3; the average for the four years being 10 parts per million as against 8.3 for the Illinois in 1899, and an average of 7.4 for the three years subsequent to the opening of the Chicago main drainage channel.

The oxygen consumed by suspended matters in the waters of the Misissippi were in 1899-5.4; in 1900-5.8; in 1901-3.5; in 1902-4.5; the average for the four years being 4.8; the proportion in excess of that required by suspended matters in the water of the Illinois river during 1899, which was 4.3, and also considerably greater than the average for the Illinois 8790 river for the three years, 1900, 1901 and 1902, the figures for that year being 3.3.

The free ammonia contained in the waters of the Mississippi river at Grafton, reached the proportion of .077 for the year 1899, the average for the year 1900 being .133; for the year 1901-.182; for the year 1902-.095; the average for the four years being .116, as against the average for the Illinois river in 1899 of .313, and the average for the three years, 1900 to 1902, being .332.

The albuminoid ammonia in the waters of the Mississippi river for the year 1899 were on the average .508, the average for 1900 being .448; for 1901-.403; for 1902-.464, the average for the four years being .455, a quantity slightly less than that contained in the Illinois river water in 1899, which latter was .479, but considerably in excess of the proportions found on the average in the Illinois river water for the three years, 1900, 1901 and 1902, which average was .37.

Albuminoid ammonia derived from dissolved substances in the Mississipi river at Grafton for 1899 was .217; 1900-.222; 1901-.202; 1902-.189; the average for the four years was .207; the average for the water of the Illinois river for 1899, 8791 was .247, and for the three years subsequent thereto, that is, 1900, 1901 and 1902, it was .22; the proportions in the Illinois river being slightly greater than the proportions in the Mississippi.

The albuminoid ammonia derived from suspended matters was for the Mississippi river in 1899, .291; 1900-.226; 1901-.201; 1902-.275; the average for the four years being .248, as against .232 in the Illinois river in 1899, and .149 the average for the Illinois river for the three years 1900 to 1902 inclusive.

Total organic nitrogen in the waters of the Mississippi at Grafton were for 1899, 1.168; for 1900-1.03; and .969 for such portion of 1901 as is covered by the data in table 49 of this series. The average for these three years or such portion thereof as the data pertains to being 1.0155 as against the average for the Illinois river in 1899 of 1.148, an average for two years, 1900 and 1901, of .957.

Organic nitrogen derived from dissolved substances in the Mississippi river at Grafton for 1899, .485; 1900, 4.76; 1901-.431; the average of these being .464, as against .596 for the Illinois river in 1899, and .512, the average for the Illinois river for the years 1900 and 1901.

Total organic nitrogen derived from suspended matters for the Mississippi river water at Grafton for 1899 is .683;
8792 for 1900 .555; 1901-.538; the average being .592, as against
.552 in the Illinois river water for 1899, an average of .444 for the Illinois river water for 1900 and 1901.

Nitrogen as nitrites in the water of the Mississippi at Grafton were .012, for 1899; and .007 in 1900; and .006 in 1901, and .01 for 1902, the average for the four years being .009, as against .045 in the Illinois river water in 1899, an average of .03 for the three years, 1900, 1901 and 1902.

Nitrogen as nitrates in the Mississippi river water at Grafton was on the average .34 parts per million for the year 1899; for the year 1900 the average was .471; 1901 the average was .314; 1902 the average was .469; the general average for the four years being .405 as against the average of 1.063 in the Illinois river water in 1899, and 1.237, the average in the Illinois river water for the three years, 1900, 1901 and 1902. The data of the tables show in general that the proportions of nitrogenous organic matters as represented by albuminoid ammonia and total organic nitrogen were notably higher in the Mississippi river than in the Illinois river, although in the year 1901 they were slightly higher in the latter stream. On the other hand the oxidation products of nitrogenous organic matters represented by free ammonia, the nitrites and the nitrates, were present in the waters of the Illinois in proportions which
8793 are two to three times those contained in the waters of
the Mississippi, and the total nitrogen, that is, the sum of the total organic nitrogen, the nitrogen as free ammonia and the nitrogen as nitrites and as nitrates was 2.546 parts per million in the waters of the Illinois as against 1.585 in the waters

of the Mississippi. The preponderance of nitrogen in the waters of the Illinois over the proportions contained in the waters of the Mississippi is doubtless due to the fact that the watershed of the former is more extensively and more intensively cultivated than that of the latter, and that the industrial wastes which are discharged into the Illinois are more highly nitrogenous in character than are many of those which find their way into the Mississippi. For example, the refuse matters discharged into the Illinois river at Peoria and Pekin consist largely of the highly nitrogenous wastes from glucose factories and those resulting from the feeding of cattle upon distillery slops, while the organic matters contained in the waters of the upper Mississippi are derived largely from the wastes of the lumber industries and these are not nearly so highly nitrogenous in character. Both streams of course, receive in the aggregate enormous quantities of sewage.

MR. JEFFRIES: I move to strike out the statement of 8794 the witness with reference to the nitrogenous character of the discharges from the glucose factories of Peoria and Pekin, for the reason that the defendants' evidence shows that there are no discharges from these factories, save that of pure distilled water.

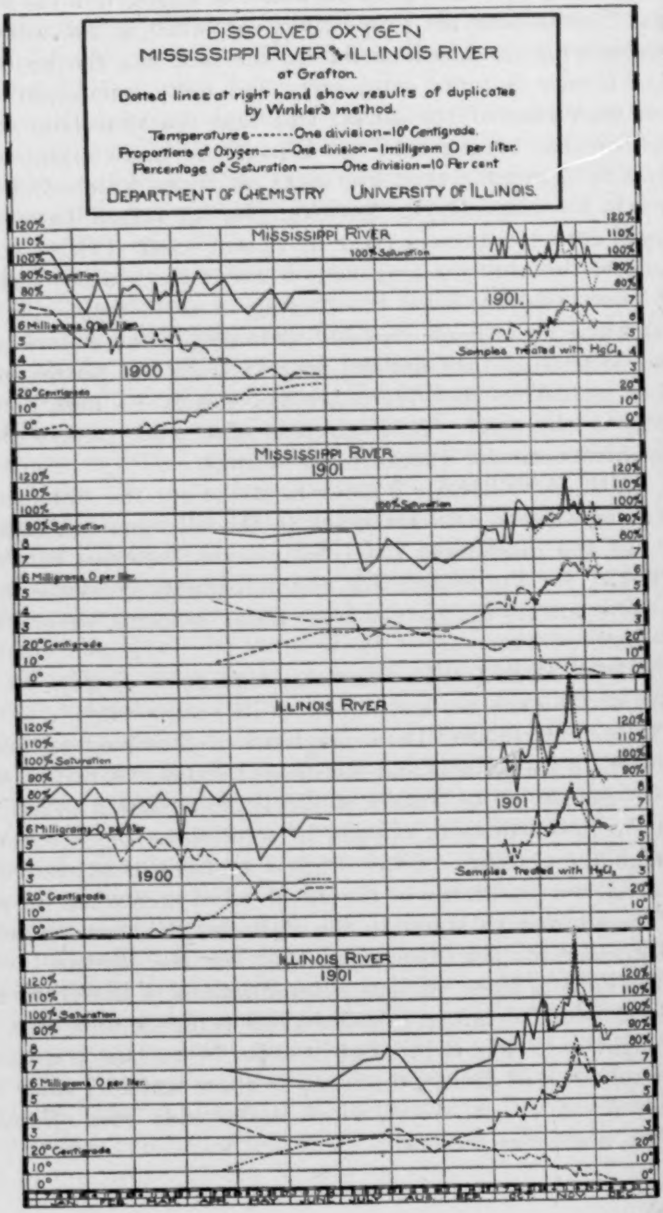
JUDGE SPRINGER: The objection goes simply to the weight of the evidence and not as to its competency.

THE WITNESS: Determinations of dissolved oxygen in the waters of the Illinois and Mississippi rivers at Grafton, show that in general of the waters of the Illinois contain practically the same proportions of oxygen in solution as the Mississippi although the stability of the organic matters as measured by the partial disappearance of the dissolved oxygen when the samples are allowed to stand in the dark for 24 hours, is somewhat greater for the Mississippi than for the Illinois.

The data of these various determinations of dissolved oxygen have been hertofore introduced as evidence and need not be brought in here in detail, but in order to explain graphically the proportions of dissolved oxygen in these waters I refer now to plate No. XXV, A. W. P., which has already been offered in evidence and is as follows: .

8795

Plate XXV.—A. W. P.



8796 THE WITNESS: And I wish to refer to my previous statements regarding dissolved oxygen in the waters of these two streams at this point.

JUDGE SPRINGER: Professor, I now call your attention to tables 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61 and 62, which contain chemical examinations of water from the Mississippi river at Alton, at times indicated in these tables. Have you prepared professor, a table of averages based upon these detail data?

A. I have prepared no tables of averages with respect to these Nos. 51 to 62 inclusive, except the averages which appear at the bottom of each of the tables.

Q. Well, it appears from the head lines over each of these tables, that the samples were taken at cross-sections of the river. Can you explain that part, and also whether they reveal the fact of the mixing of the waters of the Illinois river with those of the Mississippi river?

A. With respect to the data included in the tables 51 to 62 inclusive, I may say that for several years samples of water were collected from the Illinois river at the intake of the old Alton city waterworks, and also a few samples were collected at mid-stream, but that in the fall of 1898, arrangements were made for the collection of a series of samples at a point
8797 opposite the new waterworks nearly a mile above the town. At this place five samples were collected at five different points across the stream for the purpose of determining the differences in composition due to the incomplete mingling of the waters of the Illinois river with those of the Mississippi river. The point at which these samples were taken was 16 to 17 miles below the mouth of the Illinois river at Grafton and six or seven miles above the mouth of the Missouri river or fifteen or sixteen miles above the intake of the St. Louis waterworks at the chain of rocks.

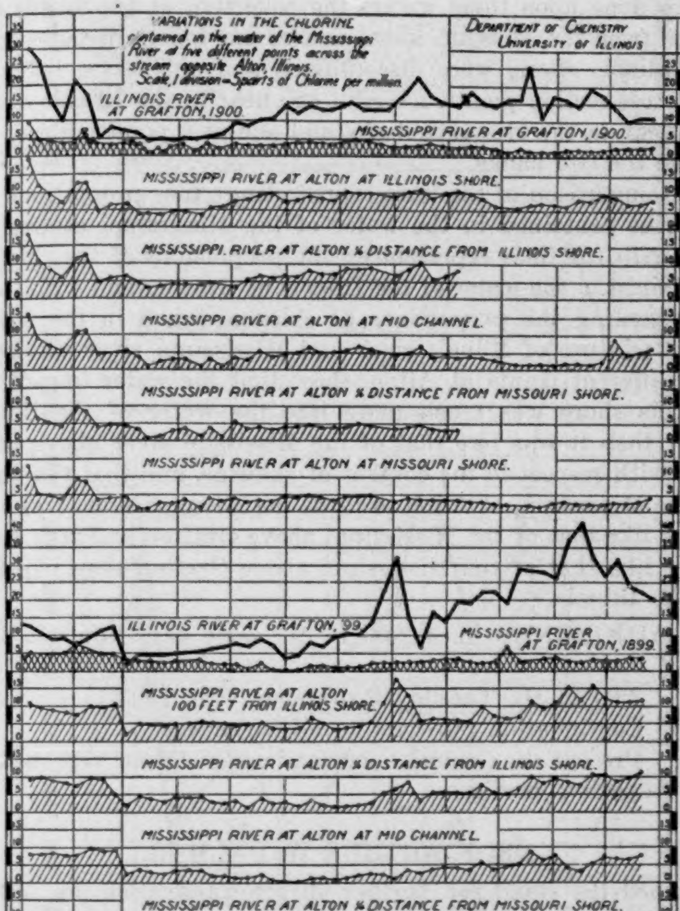
Consideration of the data of the twelve tables shows how incomplete is the mixing of the waters of the Illinois with the waters of the Mississippi, the facts being brought out especially by comparison of the proportions of chlorine contained in the waters of the Illinois river and the Mississippi river above Grafton with those found at different points in the cross-sec-

tion of the stream at Alton. In explanation I will refer to plate No. XXVI which has heretofore been offered in evidence. This plate No. XXVI gives comparative curves representing the results of chlorine determinations in the regular weekly samples collected throughout the years 1899 and 1900, the data appearng in detail in the tables 53 and 62 inclusive. Several times in January and February when because of stationary ice
8798 or floating ice it was impracticable for the collector to reach the proper points, collections were made at the ferry crossing opposite the town, nearly a mile below the point at which collections were at other times made, so that the data for portions of these two months for both years, show the proportions of chlorine, which are not truly representative for the Missouri side of the stream, because the collector who started from the Illinois side couldn't get far enough out toward the Missouri shore.

Plate No. XXVI is as follows. It has heretofore been offered in evidence:

8799

Plate XXVI.—A. W. P.



8800 THE WITNESS: In the latter part of the year 1900, as it was found necessary to contract the amount of work being done upon these waters the collection at one-fourth distance from the Missouri shore and at one-fourth distance from the Illinois shore, were discontinued and only three taken at the cross-section points, namely: one near to the Illinois shore; one near to the Missouri shore, and one at a point midway between the two banks.

Comparison of the lines representing the proportions of chlorine contained in the water of the Mississippi at Grafton and with the lines representing the proportions of the chlorine contained in the water of the Illinois at Grafton and with those representing the proportions of chlorine found in the incomplete mixture of Illinois river and Mississippi river waters at the different points at Alton, show that the water toward the Illinois shore was much more like the water of the Illinois river than it was like that of the Mississipi river above Grafton, with respect to the content of chlorine, and that the water of the Mississippi at Alton towards the Missouri shore was very much like that of the Mississippi above Grafton and very much more like that of the Mississippi above Grafton than like that of the Illinois.

ADJOURNED until 2:00 P. M., same day, Nov. 17. 1903.

2:00 P. M., Tuesday, November 17th, 1903.

8801 Continuation pursuant to adjournment.

Present the Commissioner and same counsel representing the respective parties.

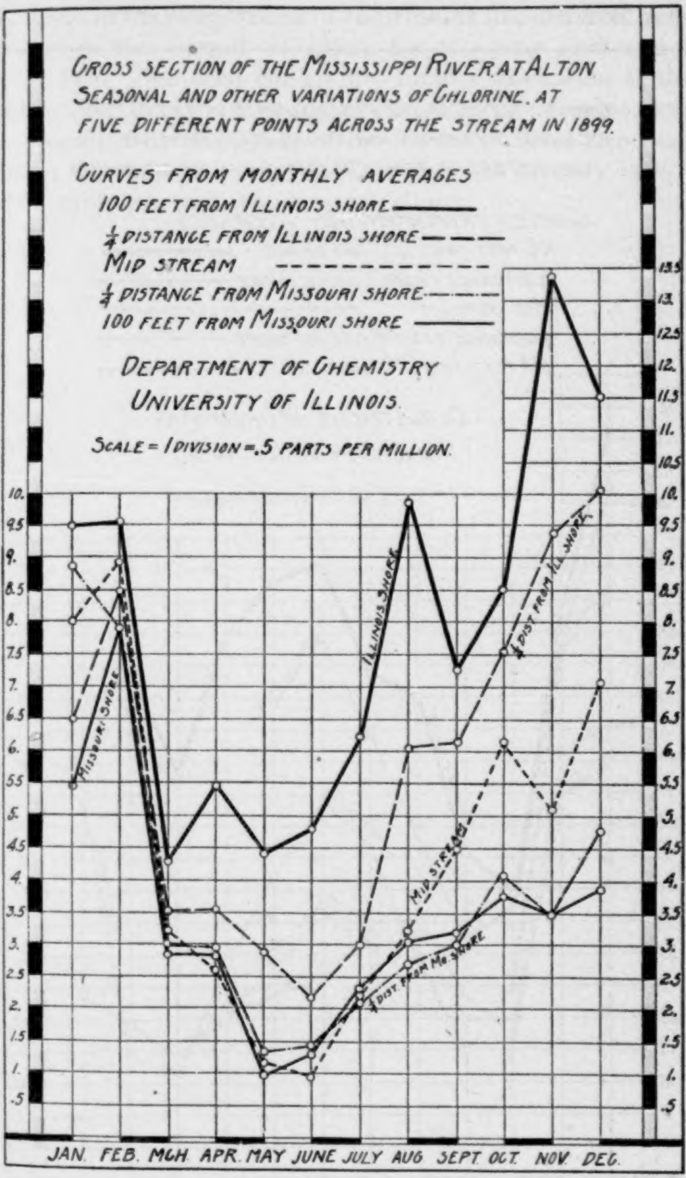
PROF. ARTHUR W. PALMER,

resumed the stand for further direct-examination by Judge Springer and testified as follows:

Q. At the time of the noon adjournment, we had reached consideration of plate XVII. Will you proceed with the explanation of that plate, professor?

A. Plates XXVII and XXVIII, which have already been introduced in evidence, are as follows:

Plate XXVII.—A. W. P.



8803 Plate XXVIII.—A. W. P.

Plate XXVIII.

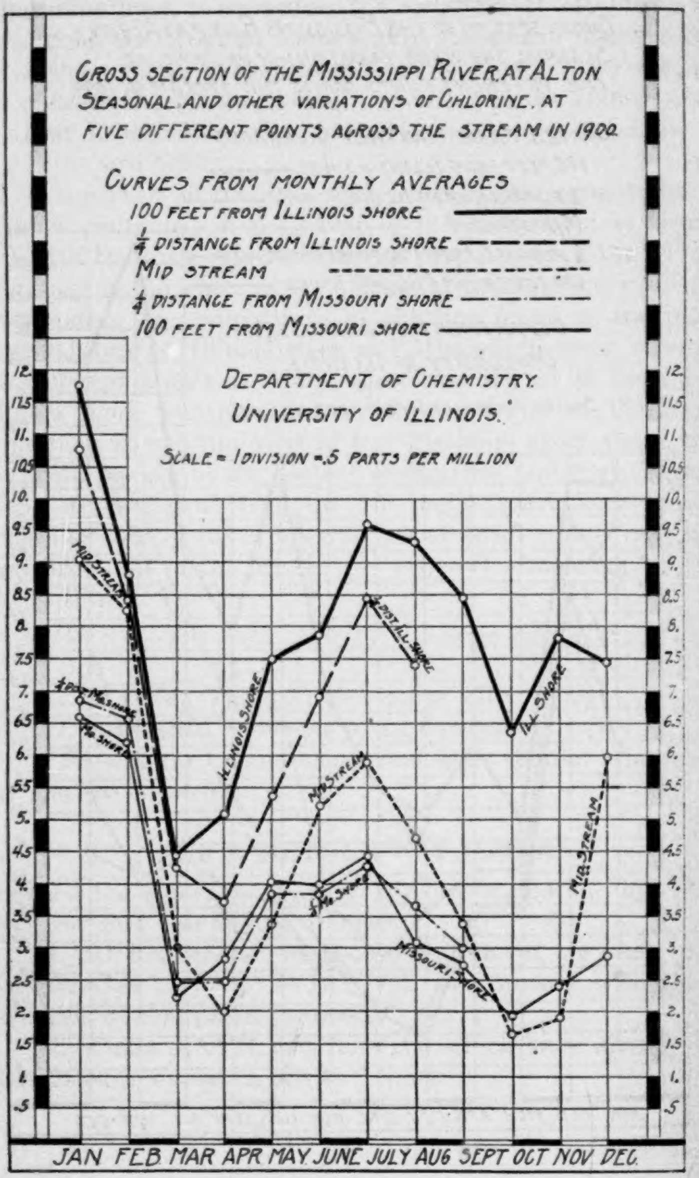


Plate XXVII, represents cross section and seasonal varia-
8804 tions in the proportions of chlorine, at five different points
across the stream, at Alton, for the year 1899 and for
the year 1900. We need not go into further discussion of those
except to say that it is monthly averages of the chlorine, which
are represented by the points of the curves of these two plates.

Next we come to plate XXIX, which has already been offered in evidence, and which is as follows:

8805 Plate XXIX.—A. W. P.

COMMINGLING OF ILLINOIS AND MISSISSIPPI.

CROSS SECTION OF THE MISSISSIPPI RIVER AT ALTON SHOWING THE RELATIVE PROPORTIONS OF UPPER MISSISSIPPI RIVER WATER AND ILLINOIS RIVER WATER AT FIVE DIFFERENT POINTS ACROSS THE STREAM. CALCULATED FROM THE AVERAGE CONTENTS OF CHLORINE AT THE FIVE POINTS, AS DETERMINED FROM WEEKLY ANALYSES THROUGHOUT THE RESPECTIVE YEARS SEE TABLES PAGES 172-191

THE LOCATION IS SIXTEEN MILES BELOW THE MOUTH OF THE ILLINOIS RIVER AND SEVEN MILES ABOVE THE MOUTH OF THE MISSOURI RIVER.

DEPARTMENT OF CHEMISTRY
UNIVERSITY OF ILLINOIS

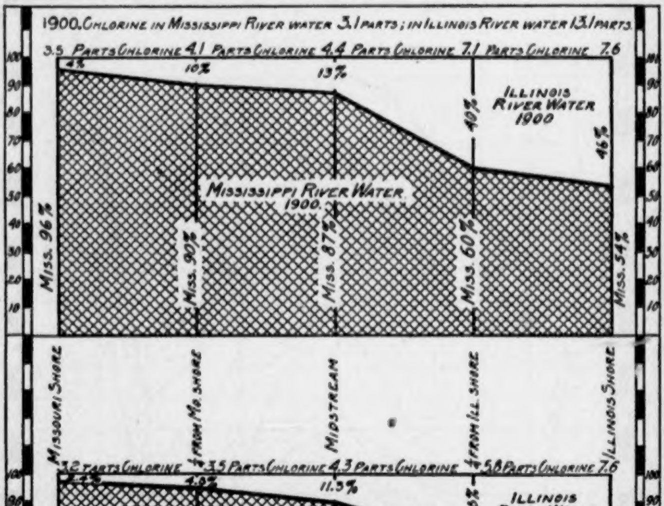

Plate XXIX represents the proportions of Illinois river
8806 water and Mississippi river water which constitute the
mixture at different points across the stream at Alton,
that is opposite the pumping station of the Alton city water
works.

The quantities of water, that is the proportional quantities of Illinois river water and Mississippi river water have been calculated from the average content of chlorine for the year for each one of the five points in the cross section. They show that comparatively little of the water of the Illinois river reaches the Missouri side of the Mississippi at this point. For the year 1899 2.4 per cent. of the water near the Missouri shore came from the Illinois river; the other 97.6 per cent. consisting of water from the upper Mississippi at the point one-fourth the distance from the Missouri shore, the Illinois river water amounted to 4.8 per cent., while the Mississippi river water was 95.2 per cent. of the mixture; at the mid-stream, that is a point midway between the two banks the proportion of Illinois river water was 11.3 per cent; that of the Mississippi, that is the upper Mississippi river water was 88.7 per cent. At a point one-fourth distance from the Illinois shore, the Illinois river water amounted to 23.5 per cent., while the Mississippi river
water amounted to 76.5 per cent. Near the Illinois shore
8807 the Illinois river water preponderated, amounting to 30
per cent. of the water passing down at that point; the
Mississippi water constituting 62 per cent. of the mixture.

For the year 1900, similar facts appear, except that there was a little more of the Illinois river water towards the Missouri shore, the percentage being four per cent. Illinois river water near the Missouri shore; 96 per cent Upper Mississippi river water.

At one-fourth distance from the Missouri shore the Illinois river water constituted ten per cent. of the mixture, while the Mississippi river water constituted ninety per cent. At mid-stream there was 13 per cent. of water from the Illinois river and 87 per cent. of water from the upper Mississippi.

At one-fourth distance from the Illinois shore the mixture consisted of 40 per cent. Illinois river water and 60 per cent. water from the upper Mississippi; while close to the Illinois shore, the mixture contained 46 per cent. of Illinois river water and 54 per cent. of water from the upper Mississippi.

It is evident from the data of the tables 51 to 62 inclusive, and is expressed graphically by the figures and the lines of this plate, that the Illinois river water does not mix perfectly with
the Mississippi river water, but passes down mainly to-
8808 ward the Illinois shore or along side the Illinois shore
on its way down stream [illegible] the bed of the Mississippi river.

Q. How far is the point at which these samples were taken from the mouth of the Missouri river?

A. This point is six to seven miles above the mouth of the Missouri river.

Q. State whether the mixing of the waters of the Illinois and Mississippi rivers is completed by the time they reach the mouth of the Missouri river?

A. From certain analyses of samples of water taken in the Mississippi river about half a mile above the mouth of the Missouri river, it is my opinion that the mixing of the water of the Illinois with the water of the Mississippi is by no means complete by the time these bodies of water reach the mouth of the Missouri.

Q. Upon what basis could you calculate the proportional mixing of the waters of the Mississippi, the Missouri and the Illinois at the chain of rocks where the St. Louis intake is located?

A. In my opinion there is no thoroughly satisfactory basis for a calculation of the relative proportions of Illinois river water, Mississippi river water and of Missouri river water, in
the mixture which pases the intake tower of the St. Louis
8809 waterworks, but for such calculations the chlorine con-
tent would in all cases be the most satisfactory basis because the chorine is not a variable constituent, or rather does not vary from causes which bring about variations of all other constituents which it is customary to determine in sanitary water analysis.

Q. Would it be practicable to calculate the mixing of the waters of the three rivers at the chain of rocks from the proportions of free ammonia?

A. It would not, because free ammonia changes, sometimes rapidly, sometimes slowly, but does change as a result of decomposition of organic matters contained in the water, in a way totally different from chlorine and it could not be assumed with good reason that a quantity of free ammonia found at one point or at one time would not change from processes going on within the water. On the other hand, chlorine does not change from any processes going on within the water itself, but only through the addition of more chlorine by the introduction of liquids or substances foreign to the water itself, or by concentration due to evaporation of the water containing the chlorine.

Q. Would it be practicable to calculate the mixing of the waters of these three rivers from the proportions of
8810 nitrites?

A. It would not for reasons similar to those just stated with reference to the ammonia. The variability of the proportions of nitrites standing in the way of the nitrites constituting a reasonably safe basis for calculation of the quantities of the water and the mixing of waters containing originally different proportions of nitrites.

Q. Would it be practicable then to calcuate the mixing of the waters of these three rivers from the proportions of total solids?

A. It might be; in case the proportions of total solids were sufficiently different in the three streams which were coming together, but even then there would be very great difficulties in the way of making a reasonable approximate calculation or a reasonable approximation of the true proportions, for the reason that the total solids include matters which are in suspension, and which by reason of variations in velocity of the stream, variations in the character of the material lying in the bottom of the stream and constituting the banks of the stream, which cause variations in the proportions of suspended matters even within short distances.

Q. What reliability could be placed upon a calculation as to the mixing of the waters of these three rivers from the proportions of suspended matters?

8811 A. That would be unsatisfactory for the reason just stated in referring to the possibility of calculating the

mixing from the total solids, which total solids of course include the suspended matters. The different velocities at different times in the year and at different points even within short distances of each other, and the different character of the material with which the water is in contact, bring about in many cases a deposition of much of the suspended matters, forming as is well known, sand-bars and other deposits in the stream, and on the other hand, where the character of the banks or of deposits in the bed of the stream are such that they can be easily removed by water, oftentimes the water picks up and holds in suspension considerable quantities of foreign matters which it may derive not from tributaries at some distance, but from localities and deposits quite near to the point at which determinations are made. That is to say, there is no certainty and in this particular case there would be no certainty that the quantities of suspended matters found in the waters of the Illinois at Grafton would proceed down in the Mississippi river to the St. Louis water works. There is no certainty that the quantities of suspended matters contained in the waters of the Mississipi above the mouth of the Illinois would remain in those waters until such time as this body
8812 of water reaches the intake of the St. Louis waterworks,
and there is no certainty that such suspended matters as are contained in the waters of the Missouri river above its junction with the Mississippi remain in that water until such time as it reaches the intake tower of the St. Louis water works; for these reasons: Calculations based upon the suspended solids and upon the total solids which include suspended solids, have no sound basis in fact, and on the other hand, at times the body of water passing down the bed of the Mississippi above the mouth of the Missouri may between the mouth of the Illinois and the mouth of the Missouri pick up and hold in suspension matters which would then be in excess of the quantities found in the waters of the Illinois and of the Mississippi at and above Grafton, and likewise the mixture of the three bodies of water between the mouth of the Missouri river and the intake tower of the St. Louis waterworks, may in this stretch of six or seven miles,—perhaps eight or nine miles, pick up from the sand-bars and the banks of the river, sus-

pended matters which were not contained at this time, at least, in the waters of either the Missouri or the Illinois or the Mississippi.

Hence, in my opinion, it is totally impracticable to calculate the relative proportions of water from these sources contained in the mixture passing down the Mississippi river 8813 beside the intake tower of the St. Louis waterworks, though by general study of all these constituents of the water, it is practicable to get a general idea as to the relative quantities constituting the mixture at this point, that is to say, a rough general approximation may at times be arrived at by consideration of all these constituents, as the basis for a calculation, but only a rough general approximation, can in my opinion be arrived at from these considerations—

MR. JEFFRIES: In view of what the witness has just stated with reference to the uncertainity of the disappearance of nitrogen as albuminoid and free ammonia, and as nitrites and nitrates, and of the suspended matter, and total solids, and the uncertainty of their appearance as well as disappearance, in the various forms, we move to strike out all of the testimony of this witness because it is immaterial, incompetent and irrelevent, and because of the uncertainties to which the witness has called attention and stated in evidence, it is unreliable and can be considered of no value or importance in passing upon the questions at issue in this case.

JUDGE SPRINGER: The objection of the counsel goes only to the weight of the evidence, and it also fails to state what the witness was showing by the statements just made, in reference to the presence of these constituents in 8814 water. They were submitted for the purpose of showing their unreliability as a basis for determining the exact mixing of the waters of the several rivers at the St. Louis intake and not for the purpose of showing their reliability as factors in this case.

MR. JEFFRIES: Then if unreliable for the purposes of showing the relative proportion of water passing down the three rivers, they must necessarily be unreliable as determining the presence or nonpresence of Chicago sewage at Grafton or at any other point where samples were taken and analyzed, for the reason that if they do not at all times correctly show the condition of the water with reference to its chemical constituents then such testimony should not be considered by the Court in determining whether or not the sewage of Chicago passes down the Illinois river and the Mississippi river and thence along the Missouri shore.

JUDGE SPRINGER: Counsel misapprehends the object of this testimony. It is not to show that these elements are not present, but it is to demonstrate the unreliability of these factors in determining how much of the water of one stream is at a particular point in the Mississippi river—at the chain of rocks.

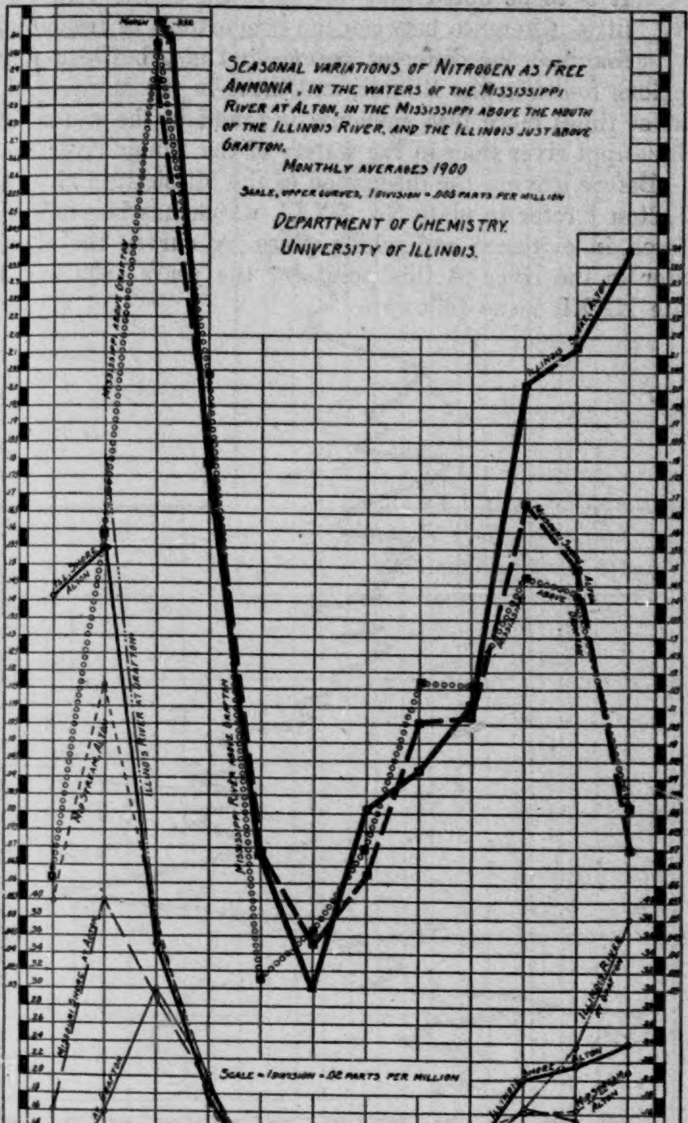
MR. JEFFRIES: For the information of counsel I will state that I understand the question and I understand 8815 the answer of the witness and I state again that if the chemical constituents to which the witness has referred are not of sufficient reliability to determine the proportionate quantities of water at the particular place mentioned in the question and in the answer, they are not of sufficient reliability to determine the chemical condition of the water at any point in the river, and therefore the chemical information that is obtained from the data which the witness has introduced in evidence, is unreliable in that it does not correctly determine the chemical condition of the water at that place.

JUDGE SPRINGER: Counsel's objection is merely argumentative and not available for any purpose. It would only go to the weight of the testimony, and as we are not now weighing this testimony but taking it, we will submit those questions to the Court in the trial of this case.

Q. Professor, proceed with your answer?

A. The seasonal variations of free ammonia and also the cross section variations of free ammonia at Alton are shown in part upon plate XXX, which is as follows:

Plate XXX.—A. W. P.



SEASONAL VARIATIONS OF NITROGEN AS FREE AMMONIA, IN THE WATERS OF THE MISSISSIPPI RIVER AT ALTON, IN THE MISSISSIPPI ABOVE THE MOUTH OF THE ILLINOIS RIVER, AND THE ILLINOIS JUST ABOVE GRAFTON.

MONTHLY AVERAGES 1900

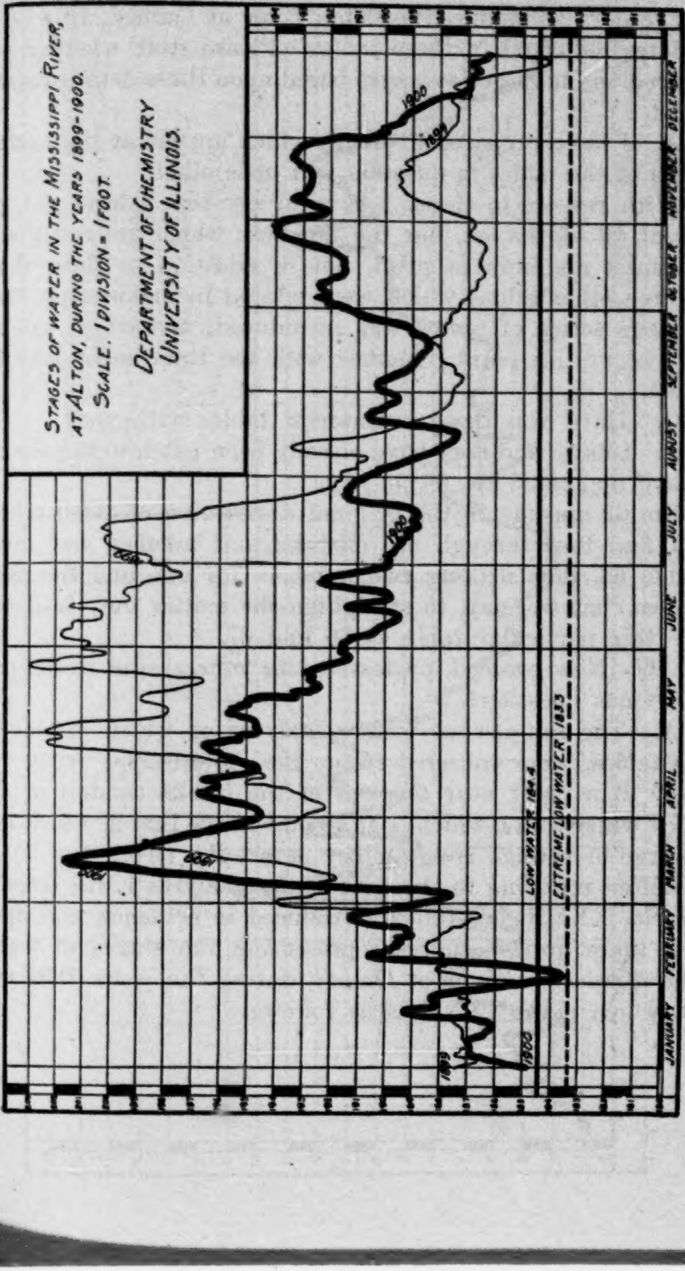
SCALE, UPPER CURVES, 1 DIVISION = .005 PARTS PER MILLION

DEPARTMENT OF CHEMISTRY.
UNIVERSITY OF ILLINOIS.

It is to be noted that during much of the year there is
8817 little difference between the proportions of free ammonia found at the different points, and also between the proportions found in the Illinois, and those in the Mississippi, and that at times more free ammonia is found in the waters of the Mississippi river than in the waters of the Illnois river.

Before leaving the discussion of the Mississippi river water at Alton I refer to plate No. XXXI, which has heretofore been offered in evidence and which gives by curves the stages of water in the river at this point for the years 1899 and 1900; plate XXXI, is as follows:

Plate XXXI.—A. W. P.



Q. Professor, I call your attention to tables Numbered 63,
8819 64, 65, and 66, which contain chemical examinations of
waters from the Mississippi river at Quincy, Illinois at the dates indicated in these tables. Please state whether you prepared any tables of averages based upon these detailed statements?

A. I have prepared averages which appear at the bottom of each of the tables in question, but none other.

With respect to these, I have to say that I have not got in print all of the set, but the numbers which are mentioned by counsel are here in print, but in addition to these there are three other tables which were offered in manuscript when the entire series of plates was introduced, and which are referred to at this point, together with the three mentioned by counsel.

Q. Have you those manuscript tables with you?

A. I have, and they have already been put into the record, and are numbered 68, 69 and 70.

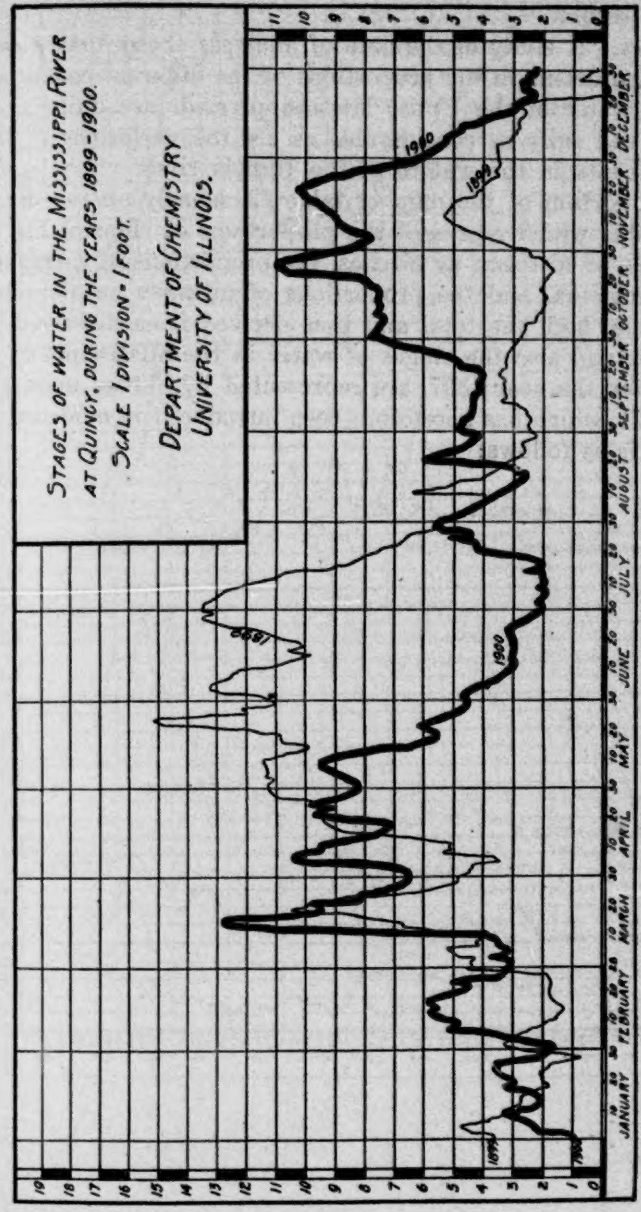
No. 67 appears in the original description of these tables, but I find that through my mistake that number was given to table 66, thus making two numbers for one and the same table, so that we may, to straighten the matter out, designate this particular table as 66 and 67.

8820 Q. Now proceed, professor with your answer to the previous question?

A. The samples of water, analyses of which appear in these tables, were collected from the Mississippi river at Quincy at a point near the end of the intake conduit of the Quincy waterworks, which is at a point above that at which any discharge of sewage from Quincy enters the river.

Before referring to the data of the analyses I will refer to plate No. XXXII, heretofore introduced in evidence, and upon which there appear ~~curves~~ representing the stages of water in the Mississippi river at Quincy during the years 1899 and 1900, which plate XXXII is as follows:

8821 Plate XXXII.—A. W. P.

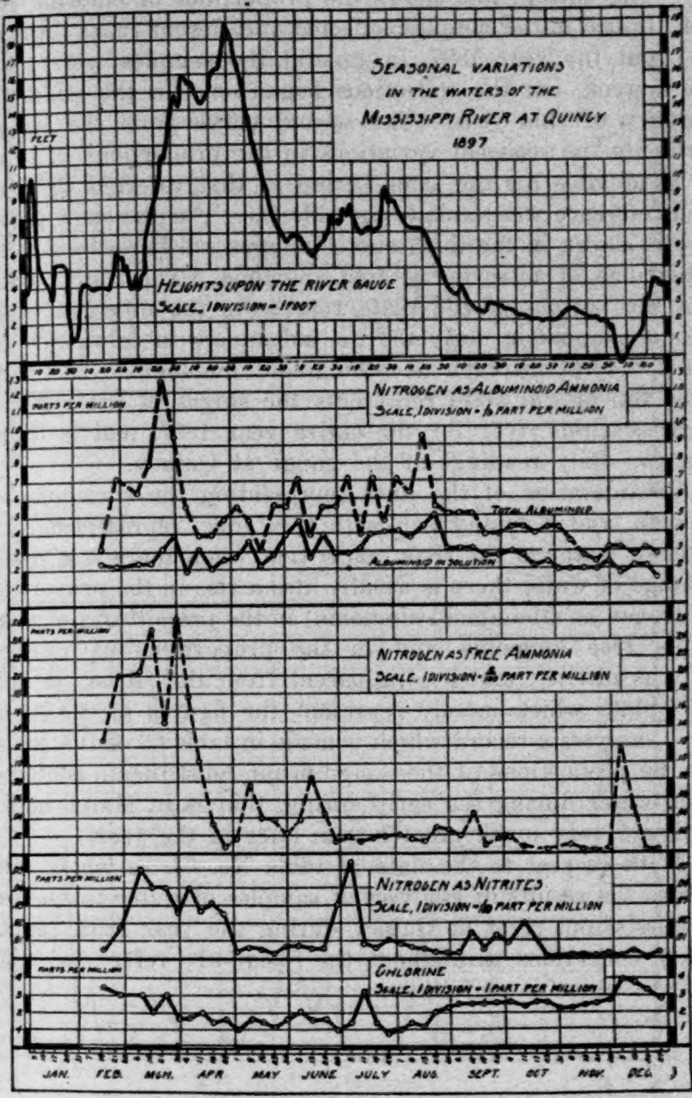


Q. What significance do you attach to these tables, professor? 8822

A. A study of the data of analyses shows that the seasonal variations in the proportions of the different constituents of the water of the Upper Mississippi river are quite as frequent and fully as considerable as are the variations of these constituents in the waters of the Illinois river.

A portion of the data of table 63, namely all the data of that table which represent the proportions of chlorine the proportions of nitrogen as nitrites, the proportions of nitrogen as free ammonia, and the proportions of nitrogen as albuminoid ammonia, both the total and that derived from dissolved substances, and also the stages of water in the Mississippi at this point for the year 1897, are represented by curves upon plate XXXIII, which has heretofore been introduced in evidence, and which is as follows:

8823 Plate XXXIII.—A. W. P.



The bottom line shows the proportions of chlorine con-
8824 tained in the samples collected at different times through-
out the year 1897, in general the samples were taken once a week, but the collections began only in the middle of February of this year. The second curve from the bottom represents the seasonal variations in the proportions of nitrogen as nitrites for the same period as that referred to above when reference was made to the chlorine. For the same period there is shown in the third curve the seasonal variations in the proportions of nitrogen as free ammonia. The fourth curve from the bottom of the plate represents the nitrogen as albuminoid ammonia derived from substances in solution. The fifth the total nitrogen as albuminoid ammonia. The curve at the top of the plate represents the stages of the water in the Mississippi river for the entire year 1897, and is drawn from the daily readings of the gauge at Quincy.

Consideration of the lines representing the chemical constituents, and a comparison with the line representing the stages of water in the river, show that when there is a rise in the stage of water there is usually also a rise in the proportions of nitrogen as albuminoid ammonia; in the proportions of nitrogen as free ammonia and in the proportions of nitrogen
as nitrites, and it is apparent from the lines in this
8825 plate which merely represent the figures of the actual
analyses a record which is made in table 63 of this series, that the proportions of these significant constituents contained in the water during the early spring, that is in March and in April, are very much greater than later in the year.

With respect to the data of table No. 64, in which there is given the results of analyses of samples of water taken from the Mississippi river at Quincy during the year 1898, regular weekly collections throughout the year—I refer to plate XXXIV, which is as follows:

Plate XXXIV.—A. W. P.

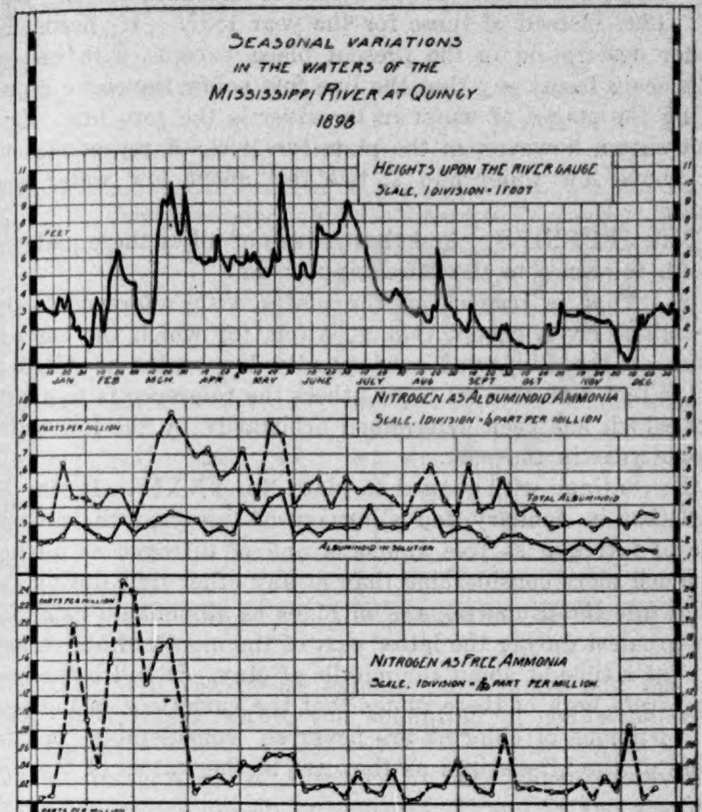


Plate XXXIV is similar in all repects to plate No.
8827 XXXIII, except that it refers to the data for the year
1898 instead of those for the year 1897. It needs no further description in the present place, except—with respect to the scale I may say that the line just below the curve representing the stages of water in the river is the zero line. Zero is not shown however, in the plate for 1898,—1 represents one foot above low water and 2, two feet above low water, and so on.

MR. JEFFRIES: And that is true of all of these plates is it, with reference to the Mississippi river?

A. That is true of all the plates with reference to the Mississippi river, except that at Alton, for which the basis is Biloxi, on the Gulf, and consequently low water at Alton is put 184 feet, but with all these others the reference is to a zero point which has been determined arbitrarily by the low water in some year in the past.

To continue with regard to plate No. XXXIV. It may be noted that in January and February of this year the proportions of nitrogen as free ammonia and of nitrogen as nitrites was much more considerable than at any other time during the year, while the proportions of nitrogen as albuminoid ammonia were greatest during the latter part of the month of March and
at a time at about the middle of May. It will be noticed
8828 from both of these plates that the variations in the proportions of chlorine are never so considerable in the waters of the Mississippi as they are in the waters of the Illinois.

Comparison of the data for the Mississippi river at Quincy with those for the same stream at Grafton show substantially a similarity of the water at these two points, more than 100 miles apart, both as to the proportions of the different constituents and the variations of the same.

Q. JUDGE SPRINGER: Professor, I now call your attention to tables numbered 71, 72 and 73, of the series now under consideration which contain chemical examinations of the waters from the Kanakakee river at Wilmington in the State of Illinois. Please state whether you have prepared any table of averages based upon the detailed data in these tables?

A. I have, and it is defendants' table of Averages No. 12, and is as follows:

8829

DEFENDANTS' TABLE OF AVERAGES NO. 12.—A. W. P.

TABLE VII.

CHEMICAL EXAMINATION OF THE WATERS OF THE KANKAKEE RIVER AT WILMINGTON. YEARLY AVERAGES. PARTS PER MILLION.

Year	Chlorine	Oxygen Consumed.			Nitrogen as Ammonia.				Organic Nitrogen.			Nitrogen as

Q. Will you please explain these tables and the table 8830 of averages which you submitted in connection therewith?

A. In the table of averages No. 12, I have the averages of the data which appear in tables 71, 72 and 73 and also averages of analyses of waters of the Kankakee river collected at Wilmington during the year 1896, the data for which appear in my preliminary report which has been heretofore presented as defendants' Exhibit A for identification.

With respect to the data of these analyses I would say that the samples of water were collected at Wilmington a point ten or twelve miles from the mouth of the Kanakakee river, and that the data of the analyses may be regarded as fairly representing the condition of the water of the Kanakakee river as it is about to unite with the water of the Desplaines river. Until the Chicago main drainage channel was opened, the sew-

age discharged through the Illinois and Michigan canal met with its first notable dilution, usually only upon mixing with the waters of the Kankakee for although at times the flood flow in the Desplaines would for a few days equal or even exceed the main flow in the Kanakakee, that is, would amount to 300,000 to 400,000 cubic feet per minute, and at times even amount to twice this quantity, and would dilute the
8831 waters discharged from the Illinois and Michigan canal
eight to ten and even sixteen to twenty times, yet the mean flow of the Desplaines for the year is but one-fifteenth to one-tenth that of the latter stream, and the ordinary low water flow is proportionally even less.

Inspection of the figures of the detailed analyses show that there are notable variations in the composition of the waters of the Kanakakee during the year. In general the variations are greatest in the spring of the year when freshets bring down much suspended matters, both mineral and chemical, but it will be noticed that there is a considerable diminution in the proportions of nitrates during the warm summer months; this diminution being in part the result of the growth of vegetation in the flowing waters of the stream; in part the result of the simulation of nitrates by the vegetation of the head waters in the Kankakee marshes, which during this portion of the year constitute the chief source of supply. The higher nitrates during the high water season are in part due also to the leeching of nitrates from the soil by the run-off, and the discharges from tile drains, both of which occur chiefly during the seasons of lower temperature and greater precipitation, which are consequently of course the seasons of
8832 high water.

With respect to these variations in the waters of the Kankakee I refer to plate No. XXXV heretofore offered in evidence, but which has not been made up into a plate and printed, and I have but this one plate. The plate will be made and copies will be introduced. This plate is as follows:

(Copy not subsequently furnished, F. S. B., Com'r.)

Seasonal variations in the Kankakee river at Wilmington; there are two sets of curves upon it; those at the left hand representing the proportions of nitrogen as nitrates; those at the right hand representing the proportions of nitrogen as free ammonia, the bottom curve of each set gives the data, or is drawn from the data in the tables referring to the year 1896. The second set of curves covers but fractions of the years in question, the years 1897 and 1895.

The third set represents these constituents for the year 1899 covering the period from the beginning of June, 1899 to the end of December. In connection with this set of curves, there is given at the left hand of the plate a curve representing the stages of water in the Kankakee river at Wilmington for the first nine months in the year 1900, where the stages of water are represented in feet above the zero.

The fourth sets of curves upon this table, namely those at the top of the plate, give at the left hand the proportions
8833 of nitrogen as nitrates contained in the waters of the
Kankakee river at Wilmington as found by the analyses of samples collected during the year 1900; the curves at the left are two in number.

The continuous line represents the proportions of nitrogen as free ammonia contained in the water of the Kankakee river at Wilmington, as found by analyses of samples collected throughout the year 1900.

The second curve and the broken line represents the temperatures of the water during the first six months of the year 1900. That is the temperature of the water in the Kankakee river at Wilmington at the time the samples for analyses were collected.

The lines upon the plate serve to illustrate the statements made above respecting the variations of the nitrogen as nitrates, and the other constituents of the water of the Kankakee at Wilmington. The organic matters contained in the waters of this stream are almost entirely of vegetable origin, for no considerable amount of sewage is discharged into this stream. That of Kankakee, with a population of nearly 14,000—it is given here 13,995—about 35 miles from the mouth and 25 miles above Wilmington, the point at which collection was made, being the most important place upon the watershed of the
8834 Kankakee river.

Q. Professor, I now call your attention to tables numbered

74, 75, 76 and 77, which contain chemical examinations of water taken from the Fox river at Ottawa, Illinois at the times indicated on those tables. Please state whether you prepared a table of averages based upon these tables?

A. I did, and it is contained in defendants' table of Averages No. 6, which contains also the similar averages for the waters of the Illinois river at Ottawa, and has already been introduced.

Q. Will you please explain these detailed data and also the table of averages based upon them?

A. The Fox river is the largest tributary of the upper Illinois proper and next to that of the Kankakee its discharge is the most important diluting factor of the upper Illinois. Its discharge is more uniform in volume than that of the Desplaines river and is greater in proportion to its water-shed area. The samples for analyses were collected above the town of Ottawa and above the aqueduct which carries the water of the Illinois and Michigan canal across the stream, the reason being that this aqueduct leaks and discharges water from the Illinois and Michigan canal into the Fox river at a point a short distance within its mouth.

8835 The waters of the Fox are rather highly charged with organic matters which are mainly derived from the vegetation which is abundant in this stream, particularly in the marshes and shallow lakes which constitute the chief source of its head water supply. The stream receives the sewage and manufacturing wastes of a number of towns, of which Elgin, with a population of 22,433, and Aurora, with a population of 24,147, are the largest. Between these two towns is the town of Geneva, where there is a large glucose works, and in which 40,000 carloads of corn are used annually, the wastes from which—probably at least 150 tons of highly nitrogenous organic refuse daily, are discharged into the river. Below Aurora, comparatively little sewage and wastes enter the stream and there is considerable opportunity in the flow of 50 miles, between Aurora and the mouth, for the natural purifying processes to exert their influence in bettering the condition of the water. The averages which appear in table 6, contain the data of tables 74, 75, 76 and 77 in the form of general averages, and also an average for the entire three years represented, that is the years 1898, 1899, and 1900.

MR. JEFFRIES: I move to strike out what the witness said with reference to the extent of the pollution in the river at this point for the reason that he has not disclosed the source of his information.

8836 JUDGE SPRINGER: The witness may now state the source of his information if he desires to do so.

A. I was informed by an individual connected with the management of the concern in question referred to, who first told me personally that about 40,000 car-loads of corn were used annually there, and that the refuse was discharged into the river, and he subsequently confirmed his information in Geneva and wrote me to the same effect. I have further been informed by the president of the Fish Commission of the State of Illinois that such quantities of corn are used in the works at Geneva, and that the refuse is discharged into the Fox river and that it kills the fish in the Fox river.

MR. JEFFRIES: I move to strike out all that the witness has said with reference to his source of information for the reason that it is utterly hearsay, and is not based upon facts from the mouths of witness in such manner as to give us an opportunity to cross-examine those witnesses with reference to the correctness of the statements. The witness has clearly disqualified his statement in his testimony in that respect.

JUDGE SPRINGER: State, professor, whether or not these data were collected by you as a part of your duties as head of the chemical department of the University of Illinois.

MR. JEFFRIES: Now I object to the witness making
8837 any such statement or giving any such testimony for the reason that there is nothing included in the statute designating the particular duties of the University of the State of Illinois, or the chemical department of that University requiring the witness to ascertain facts of this character, and for the further reason that even though the witness did embody these statements which he has just read in evidence, in his report, he has by his statement as to the manner of obtaining the information, disqualified such statements so far as being

evidence in this case or so far as the competency of such statements is concerned.

JUDGE SPRINGER: I submit that the authority conferred by the legislature of Illinois upon the University of Illinois, in reference to the examination of the waters of the State, is sufficient to authorize this witness as the head of the chemical department of the University to collect these data from the most reliable sources, and if he deems the sources sufficiently reliable to incorporate them in his official report, he may do so, and that as they are a part of his official report, the objection goes simply to the weight of the evidence and not to its competency, and would more properly have been brought out on cross-examination and not as an objection to the introduction of the evi-
8838 dence.

MR. JEFFRIES: I submit to the Court that the witness was not reading in evidence nor offering in evidence his report, but testifying as to facts concerning the case at issue, and we have a right to have the witnesses who are acquainted with those physical facts, before us, in order that we may cross-examine them and I object to this witness stating what any other person, whether he be an officer or what not, said, or told him with reference to the conditions about which he is testifying, and I will state further that if it is the purpose of the defense to offer the report of this witness to the University of the State of Illinois in evidence, that there is a proper way to do it, but that it is not competent for this witness to read from that report statements in evidence which bear the resemblance of having been collected accurately and personally by this witness without reference to his duties as a member or as one of the faculty of the University of the State of Illinois.

(Last question repeated).

8839 (Question repeated).

A. They were; as a part of my duties as head of the department of chemistry of the University of Illinois and in charge of the survey of the waters of the State of Illinois, the chemical survey of the waters of Illinois.

JUDGE SPRINGER: Go ahead professor.

MR. JEFFRIES: For the reasons just stated I object to the witness testifying to any such facts on the ground that it is not competent testimony.

THE WITNESS: I am through with that.

JUDGE SPRINGER: Now I call your attention professor, to tables 78 and 79 of this series which contain chemical examinations of waters from the Spoon river at Havana, Illinois, at the time indicated in these tables. Please state whether you made the averages or prepared the table of averages based upon these data?

A. I did. There are averages at the bottom of the table in question numbered 78, 79 and 80, the latter of which appears only in manuscript and covers a portion of the year 1899, extending from January 3rd to May 30, this latter, that is table 80, has not been incorporated in the tables of averages No. 14, but there appear in that table in addition to the averages for the Spoon river for the years 1897 and 1898, also the average
for the year 1896, the detail data of which appear in my
8840 preliminary report heretofore offered for identification
as Defendants' Exhibit A.

Collections were made in the Spoon river at a point within about a half a mile of the mouth. Spoon river drains a watershed area of about 1870 square miles, but as there are no very considerable towns situated upon the stream of its watershed, it receives but little sewage and may be regarded as one of the least polluted of the natural streams of the state.

Q. Did you make any chemical examinations of the waters taken from the Big Vermillion river, which is one of the tributaries of the Illinois river?

A. I did. Most of these examinations however, have already been reported in my testimony with reference to the streams examination report. The table of averages No. 13 A. W. P. contain the averages for the years 1899 and 1900, details of which are given in the set of tables 1 to 80 inclusive referred to above as being testified to as part of the streams examination report, and in addition, there is a set of averages for the year 1896, which have been taken from the preliminary report heretofore offered for identification and referred to as defendants' exhibit A.

8841 THE WITNESS: Table 13 is as follows and table 14 follows 13.

DEFENDANTS' TABLE OF AVERAGES NO. 13.—A. W. P.

TABLE XIV.

CHEMICAL EXAMINATION OF THE WATERS OF THE SPOON RIVER AT HAVANA. YEARLY AVERAGES. PARTS PER MILLION.

Year	Chlorine	Oxygen Consumed.			Nitrogen as Ammonia.				Organic Nitrogen.			Nitrogen as	
		Total	By Dissolved	By Suspended Matter	Free Ammonia	Albuminoid Ammonia. Total	Albuminoid Ammonia. Dissolved	Albuminoid Ammonia. Susdend'd	Total	Dissolved	Suspended	Nitrites	Nitrates
1896	4.4	7.3	......	......	.119	.351	......	......	.806	......	......	.04	1.6
1897	3.7	13.1	......	......	.148	.58	......	......	1.04	......	......	.047	1.8
1898	3.4	14.8	......	......	.119	.603	......	......	1.47	......	......	.036	.6
Av'e	3.8	11.8	......	......	.129	.511	......	......	1.10	......	......	.041	1.0

The Big Vermillion is a most important tributary be-
8843 tween Ottawa and Peoria; the discharge varies between wide limits, but it is an important factor as a diluting agent, only during the freshet season. In the drier season its flow is practically nothing but sewage, derived mainly from the towns of Pontiac and Streator, and from the drainage of factories and mines upon its banks; the stream is used as a source

of water supply for the towns of Pontiac and Streator, and during much of the year the entire flow of the stream above these towns is used for water supply, and then is discharged again into the stream as sewage below the respective towns. The samples for analyses were collected about a half a mile within the mouth of the stream, the mouth being about three miles above the wagon bridge at LaSalle.

Q. Now professor, you may submit such suggestions as occur to you in comparison of the waters of the tributaries of the Illinois river with the river itself?

A. Comparison of the detailed data of the analyses of the water of the Illinois at Averyville and at Grafton, with the data of the analyses of the waters of the tributary streams, shows that the latter are subject to seasonal variations which in most respects are as great as are those of the Illinois. Comparison of the yearly averages which are given in defendants' tables of Averages No. 15, A. W. P., shows that the proportions of organic matters as represented by oxygen consumed, albuminoid ammonia and total organic nitrogen are even 8944 more considerable in the waters of the larger tributaries than in the waters of the Illinois at Grafton, and the general averages for the six tributaries examined are substantially equal to the averages for the Illinois for 1900, 1901 and 1902.

MR. JEFFRIES: Now I move to strike out that statement for the reason that there is no evidence to show the places at which the samples of water were taken in the Illinois river with reference to the large sources of pollution on this river as testified to by witnesses for the defendants, so that the analyses of water obtained from the tributaries and those obtained from the Illinois river proper were not so taken with reference to the sources of pollution as to be comparable.

JUDGE SPRINGER: I desire to suggest that the samples as appears from the testimony of the witness, were taken in these tributaries at a point so far from the mouth of the respective rivers as not to receive any mixing of the waters of the main stream, and that these points indicate the conditions of the waters of the tributaries as they enter the main bed of the Illinois river.

MR. JEFFRIES: I object to Judge Springer testifying in

this case. The evidence of the witnesses for the defense, shows for itself, that is, the evidence of the witnesses introduced
8845 and sworn in the case is the only evidence that the court has in order to determine the distances from the mouth of the tributaries that the samples were taken and the court is not to be guided by what counsel may say upon that subject.

JUDGE SPRINGER: I was merely calling the attention of counsel to what the witness had already stated.

MR. JEFFRIES: I am much obliged to counsel for calling my attention to it, but I think I understood what the witness testified to about taking the samples, both from the Illinois and the tributaries.

JUDGE SPRINGER: Proceed now with your statement, professor.

THE WITNESS: I should have explained before, that in the tables of averages there is also given averages of analyses of samples collected from the Sangamon river at Chandersville, details of which have been given in the set of tables 1 to 6 inclusive, offered in the report of Streams Examinations for the Sanitary District.

In the table of averages it appears that the free ammonia and nitrites however, are in general more abundant in the waters of the Illinois river than they are in the tributary streams although three of the latter carry practically as much or more in nitrates as does the Illinois, thus, the proportions of nitrites contained in the water of the Illinois at Grafton during the years 1900 to 1902 being .03 parts per million; the aver-
8846 age for the water of the Big Vermillion during the years 1896, 1899 and 1900 was .025, but little less and during the years 1896, 1897 and 1898, the waters of the Spoon river contain nitrogen as nitrites in the proportion of .041 parts per million, while the waters of the Sangamon contained on the average for the years 1890 and 1900, nitrogen as nitrites in the proportion of .032.

A portion of the data included in this table of averages No. 15 A. W. P., have been used in the preparation of plate No. XXXVI, which is the duplicate of the one introduced in an earlier report, and which itself has been introduced in my testimony. The plate represents by means of columns the proportions, or the various constituents as chlorine, oxygen consumed, nitrogen as free ammonia, and nitrogen as nitrates. In the Illinois river at Averyville and at Grafton, in the Kankakee river at Wilmington, the Fox river at Ottawa, the Big Vermillion near LaSalle; the Sangamon river at Chandersville for the four months period, June, July, August and September, 1899 and 1900, and as this has been discussed elsewhere, it is not necessary to do more than to refer to it at this point.

Table No. 15 is as follows:

8847

DEFENDANTS' TABLE OF AVERAGES NO. 15.—A. W. P.

Q. You will please institute any further comparisons
8848 which you may have made based upon these tributaries of the Illinois river for points along the Illinois river itself?

MR. JEFFRIES: I move to strike out all comparisons and inferences that have been drawn by this witness upon the tables of analyses of waters in the tributaries of the Illinois river and the waters of the Illinois river, for the reason that the same is incompetent, irrelevant and immaterial and have no bearing upon the issues involved in this case, and for the further reason that the statement of the witness with reference to these tributaries being diluting factors, is not borne out by the evidence for the reason that the evidence as summed up by this witness shows the tributaries to be as greatly polluted as the Illinois river itself and for the further reason that the tributaries of the Illinois river thus shown in evidence are situated upon the natural water-shed of the Illinois river and there is no complaint alleged in the bill in this case against persons, cities or enterprises polluting the waters tributary to the natural watershed of the Illinois and Mississippi rivers, and that the fact that the tributaries of the Illinois river are thus polluted as stated by the witness is no justification for Chicago to discharge its sewage into the river or burden it with polluted material from its home watershed.

8849 JUDGE SPRINGER: I desire to call the attention of counsel to the fact that Dr. Teichmann in his testimony in this case on the 17th of March I think it was, stated that the condition of the Illinois river was worse in 1897 than before that time, and that its tributaries were not worse than in earlier years. This matter having been overlooked by counsel for the complainant it is competent for us to submit the facts which will rebut statements of their own witnesses.

MR. JEFFRIES: I would suggest that whatever evidence was introduced by complainant upon that proposition was material and not objected to by defendants at the time.

JUDGE SPRINGER: It is in the record nevertheless.

MR. JEFFRIES: The witness might have made, in summing up the evidence the declaration attributed to Dr. Tiechmann, but that does not necessarily justify the defendants in going into a strictly chemical analysis of all the tributaries of the Illinois river. Our proposition is that it is incompetent, irrelevant and immaterial so far as the issues in this case are concerned, what the condition of the tributaries is or was at any previous time.

JUDGE SPRINGER: Counsel for defendants states here that in his opinion this evidence is competent, for the reason that if it should appear from all the evidence in this case, 8850 the Illinois river at Grafton, where it enters the Mississippi river is chemically as pure as the waters of the tributaries of the streams that such testimony tends to show that whatever sewage may have entered the Illinois river from the Chicago drainage canal, has not made the condition of the river any worse than it would otherwise have been at Grafton.

MR. JEFFRIES: With that statement of counsel for defendants I suggest to the Court that all of the evidence with reference to the condition of the Illinois river and its tributaries prior to the opening of the canal is incompetent, irrelevant and immaterial so far as the issues in this case are concerned, for the reason that by the added flow in volume of water and increased rapidity of that flow down the Illinois river, while the dilution may to some extent be increased, the water as a whole is burdened with more infected material than it was prior to the opening of the drainage canal, and it is not a question of pollution merely, but a question of infection that we are dealing with in this case, and is not only burdened with the same infected material that came from the tributaries of the Illinois river and the polluting sources situated upon the watershed of that river, but in addition thereto is burdened with infected material coming from the sewage of Chicago; that is the infecting and polluting material of the city of 8851 Chicago.

JUDGE SPRINGER: By the use of the phrase "Pollutions merely," I assume that counsel still maintains that part of the allegations of the bill of complaint which charge the defendants with polluting the stream.

MR. JEFFRIES: Yes sir.

JUDGE SPRINGER: I had supposed he was about to abandon that part of it from the previous statements he has made, but as the subject of pollution is still pending, I desire to state that in my judgment it is competent to compare the condition of the water in the Illinois river after the opening of the canal with the condition of the water before the opening, for the purpose of determining whether the opening of the canal has increased the pollution or infection of the water.

Q. Professor, can you institute any comparison based upon the tables of analyses of the waters of the Illinois river with the different points on that river?

A. Yes, I have studied the proportions of various constituents as contained in the waters of the Illinois river at various points along its course.

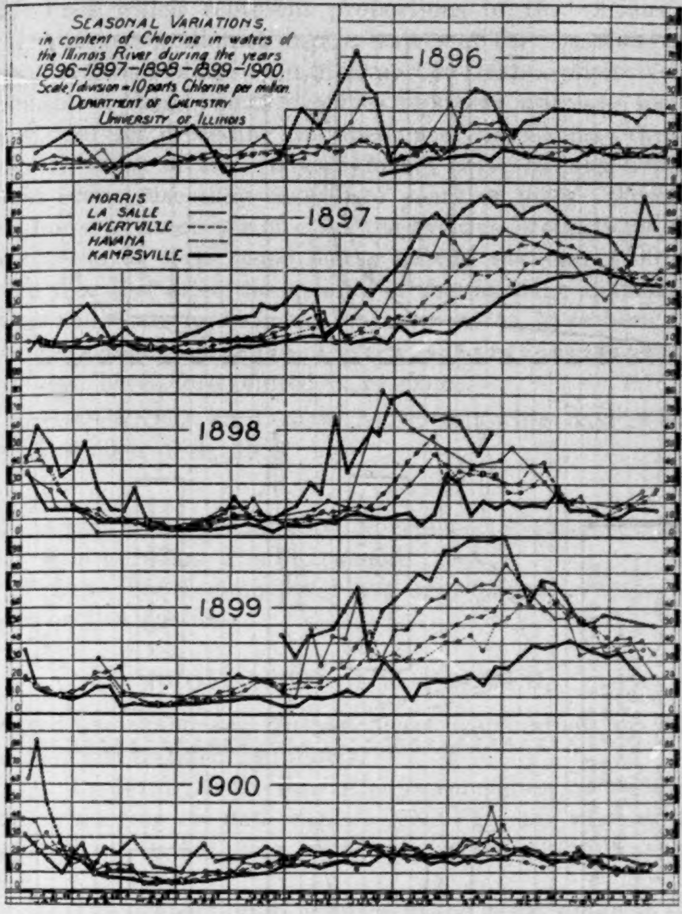
Q. Will you submit those please?

A. And in consideration of this matter, I will refer to plate No. XXXVII, which has heretofore been offered in evidence. It represents seasonal variations in the proportion of chlorine in the waters of the Illinois river at Morris, LaSalle, 8852 Averyville, Havana and Kampsville for the years 1896 to 1900 inclusive. Upon an inspection of these curves, which are representations of all the analyses made in the respective years for the points considered, the great differences in the content of chlorine, as between the first half and the second half of the year is manifest, these figures being due to the greater volume of water flowing during the first half of the year and the consequent greater dilution of the sewage, while in the second half of the year the dilution was in general very small and the proportion of chlorine naturally greater. Comparison of the line for the year 1900 with those for the preceding year shows that after the opening of the Chicago main drainage channel the proportions of chlorine were very much more uniform throughout the year, the reason being that the dilution in the latter half of the year more nearly corresponded to what it was formerly, or to the natural dilution in the earlier part of the year, that is the flow throughout the year was much more uniform in volume, and consequently the concentration of chlorine in the liquid flowing in the Illinois river never rose to such a height as it in general did during the second half of the year in times prior to the opening of the Chicago main drainage channel.

8853 Q. Professor, what plate is that you have been referring to?

A. Plate XXXVII, and it is as follows:

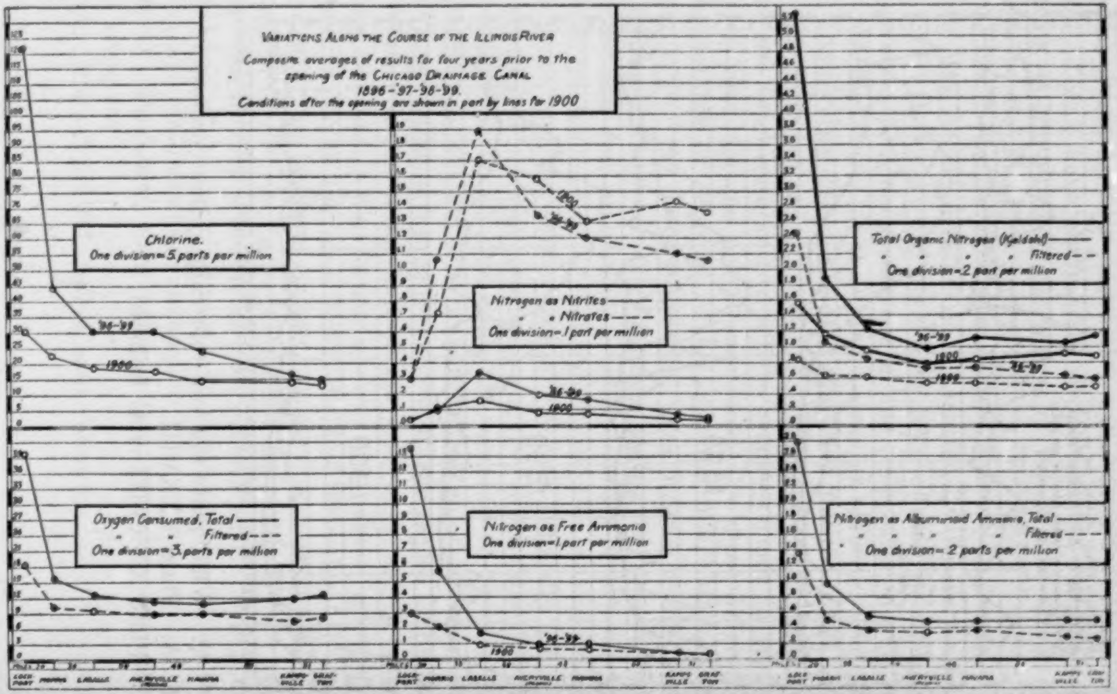
8854 Plate XXXVII.—A. W. P.



Q. What plate are you referring to now, professor?

8855 A. Plate XXXVIII.

Plate XXXVIII is as follows:



VARIATIONS ALONG THE COURSE OF THE ILLINOIS RIVER

THE WITNESS: On plate XXXVIII there are shown
8857 lines which represent proportions of the various constituents contained in the waters of the Illinois river at several different points from Lockport to Grafton inclusive. For a number of these points the lines represent averages for four years' analyses preceding the opening of the Chicago drainage channel. Some of the analyses do not cover so long a period, but in every case they cover two years or more. There are also shown in a number of cases the average proportions of the constituents at these same points during the year 1900; that is, the year just after the opening of the drainage channel. The figures which are represented by these curves, have been taken from the defendants' tables of averages 1 to 15 inclusive, which have been heretofore offered in evidence.

ADJOURNED until 10:00 A. M. following day, Wednesday, November 18th, 1903.

8858 10:00 a. m., Wednesday, November 18, 1903. Continuation pursuant to adjournment.

Present, the Commissioner and same counsel representing the respective parties.

PROF. ARTHUR W. PALMER,

resumed the stand for further direct-examination, by Judge Springer and testified as follows:

Q. Professor, at the time of adjournment on yesterday you were considering the data in plate XXXVIII and were explaining the curves on that plate. Will you proceed with this explanation?

A. The proportion of chlorine in the canal water at Lockport is shown by the figures in the table of averages and represented by the line upon the plate, and is a little more than 120 parts per million. The considerable-drop in the curve between Lockport and the next point, which is Morris, is due in small parts of course, to dilution with the waters of the Desplaines river, but is mainly due to dilution with the waters of the Kankakee between Morris and LaSalle, the next point. There come in the discharges from several minor tributaries, but the most

important diluting factor between these points is the
8859 Fox river. From LaSalle to Averyville there is practically no change in the content of chlorine, for although between these points various smaller tributaries discharge into the river, the stream also receives some sewage and waste waters which are quite highly charged with chlorides, and which consequently, nothwithstanding the increase in volume which occurs, keep up the proportion of chlorine.

Between Averyville and Havana there is a notable diminution in the content of chlorine, and from there on to Kampsville and down to the mouth, at Grafton, a somewhat continuous decrease is apparent. The proportion at Grafton being 15 parts per million.

The curve for 1900 begins at about the same point, but is intended to show the content of chlorine in the mixture at Joliet, since it is at this point that the different discharges of Chicago sewage come together. The proportion is about one-fourth that of the canal at Lockport, for the earlier period, the difference representing approximately the effect of the dilution produced by the use of the drainage channel. From this point down there is a notable diminution in the proportions of chlorine contained in the water, which in a measure keeps step with the diminution which formerly occurred, but is less considerable from
8860 point to point, and finally at the point of discharge into the Mississippi the proportion of chlorine is slightly more than 13 parts per million, which shows the effect of the dilution by the use of the drainage channel as it affected the chlorine content in the discharge from the Illinois river into the Mississippi river during the year 1900.

Oxygen consumed. The lines representing the oxygen consumed both the total and that consumed by the filtered water, show marked diminution between Lockport and Morris, a considerable and somewhat continuous diminution from Morris to Havana, beyond which point the total oxygen consumed increases slightly, so that the proportions required by the water discharged from the Illinois into the Mississippi at Grafton, are greater than they were at either Averyville or Havana, this being in part due to the luxuriant growth of vegetation in the lower stretches of the river, and in part due to the presence of other suspended matters, silt and so on, which during a portion of the year are more abundant in the lower stretches of the river than they are farther up.

Nitrites. Comparisons of the proportions of nitrogen as nitrites show that before the opening of the drainage channel there were but extremely small proportions contained in the water at Lockport, but notable greater proportions at
8861 Morris, the maximum being reached at LaSalle. This argues for the greater activity of the oxidizing processes near this point than at points far above or far below LaSalle, for while the proportions of nitrites below this point are always considerable, there is continuous diminution all the way down to the mouth of the river at Grafton.

The curve for 1900, shows similar relations between the different points, but a very notably smaller proportion of the nitrites at points below Morris. It is evident from the curves however, and these curves represent merely the figures of the tables of averages above repeatedly referred to—it is evident from these curves, however, that the zone in which the greatest activity of the nitrifying processes is reached has not been changed in position by the opening of the drainage channel. That is, it appears unmistakeably from the data of our analyses and is shown clearly in these curves, that the point where the oxidation is most active, and thorough going, is still in the vicinity of Morris and LaSalle. The data of table of averages No. 6 A. W. P. show that the point is somewhere between Morris and LaSalle, probably near Ottawa.

Q. That is to say the point of greatest activity is at or near LaSalle?

A. Ottawa.

8862 Q. Ottawa I mean, yes.

A. Yes. Nitrates. The lines representing the proportions of nitrates show a remarkable increase in the proportions contained as we proceed from Lockport and Joliet to Morris, and so on to LaSalle. The increase of nitrates between Joliet and Morris is due in part to the fact that the waters of the Kankakee river which unite with those of the Desplaines between these two points, are in certain seasons very highly charged with nitrates, but much of it undoubtedly is due to the activity of the nitrifying organisms which in this stretch of the river appear to find the conditions of food supply and dilution most propitious. The great increase of nitrates between Morris and LaSalle must be regarded as practically entirely due to the nitrifying processes which in this stretch of the river complete the destruction, that is the oxidation of the organic matters discharged into the river in the Chicago sewage at Lockport and Joliet. From LaSalle to Averyville there occurs a very considerable decrease in the proportions of nitrates. This is due not to dilution, for no considerable dilution occurs between these points,—but to the utilization of nitrates by the vegetation which is extremely abundant in the broad lake-like stretches of the river between these points.

8863 From Averyville down to the mouth of the river there is considerable further diminution in the proportions of the nitrates, and this also is due to the cause referred to above namely the luxuriant vegetation,—both that of the river banks and bed and the floating forms.

The curve representing the proportions of nitrates for 1900 shows similar sets of conditions, although the proportions of nitrates is not so great at Morris as it was formerly, a fact which is undoubtedly due to the greater dilution. At LaSalle the proportions more nearly approximate those formerly contained, and below this point, although there takes place a notable diminution in the quantity of nitrates on the way to Averyville and Havana, beyond Havana they again increase. Below LaSalle there is no point along the river at which the nitrates are not now present in considerably greater proportions than were found in the river water before the opening of the drainage channel. With respect to these differences in the proportions of nitrates between the two periods in question, it seems evident that the conclusion to be drawn must be that nitrification now takes place at least as completely and it would seem far more completely than before the opening of the drainage channel.

The fact that the proportions of nitrates are less at
8864 Havana than at Kampsville and Grafton is undoubtedly
due to the fact that the great masses of filth which are discharged into the stream in the vicinity of Peoria and Pekin owe their destruction in part to the utilization of oxygen from nitrates which are brought down in abundance by the waters passing Averyville.

Free ammonia. The line representing the proportions of nitrogen as free ammonia for the period prior to the opening of the drainage channel shows excessive proportions of this constituent at Lockport, the diminution on the way to Morris being chiefly due to the dilution, but that between Morris and LaSalle being mainly due to the oxidation of the free ammonia to nitrites and nitrates; to its assimilation by the vegetation of the river and in part undoubtedly to its elimination as free nitrogen gas. Between LaSalle and lower points upon the river the diminution proceeds continuously although free ammonia is contained in notable quantities in the water finally discharged into the Mississippi at Grafton.

The line for 1900 shows a much lower content of ammonia at the point of initial discharge of Chicago sewage, but it also shows considerable diminution on the way down the river, although as is apparent from the plate and also from table of averages No. 10 A. W. P., the proportions contained in the water
as it passes Kampsville, and is discharged at Grafton,
8865 were slightly greater in 1900 than the average for the
preceding years.

Albuminoid ammonia.

The line representing the nitrogen as albuminoid ammonia constitutes for the upper part of the river a curve quite similar to that just discussed for the free ammonia, but below Averyville there is a slight increase on the way to Havana, due to the discharge of the refuse at Peoria and Pekin. Below this point the quantity does not further diminish, but on the other hand very slightly increases. Comparison of the line for total albuminoid ammonia with that for the albuminoid ammonia derived from substances in solution shows that while the latter diminishes markedly between Havana and Grafton, the total very slightly increases, owing to the presence of greater proportions of nitrogenous suspended matters in the waters at this end of the river.

Total organic nitrogen.

The line representing the total organic nitrogen shows much the same features as those just referred to, although the proportions of total organic nitrogen are more than twice as much as those of the albuminoid ammonia.

Comparison of the curves for the period 1897 to 1899, with

the curves for 1900 shows how great an effect the dilution
8866 produced by the opening of the drainage channel has
had, and shows that this effect extends to the mouth of the Illinois river. The fact that the total organic nitrogen and the nitrogen as albuminoid ammonia, do not decrease below Havana, is undoubtedly due to the presence of the enormous masses of vegetation in the waters of the lower river. That the free ammonia does not decrease below the proportions shown for Grafton is doubtless due to its continuous production through the decomposition of the various organisms constituting the plankton, which from time to time complete their life cycles and leave their substances then to enter upon that universal series of transformations to which all organic matters are subject.

Q. Have you prepared tables of monthly averages covering these periods?

A. I have.

Q. Will you now present them?

A. They are upon these ten sheets.

Q. Just read the titles of those please.

A. I will describe them.

Q. That will be better, yes, please describe those tables of monthly averages?

A. These ten sheets contain various tables of monthly
averages which have been prepared from the detailed
8867 analyses given in tables 1 to 80 of this series, Department
of Chemistry, University of Illinois, A. W. P., 1 to 80.

Upon sheet 1, there are the monthly averages for the analyses of the waters of the sanitary canal at Joliet, the west side, for 1901; for the samples taken from the Illinois river at Averyville in 1901; for those collected from the Illinois river at Pekin during the three months, October, November and December, 1901.

On the second sheet, there appear similar monthly averages for the year 1901; samples of water taken from the Illinois river at Kampsville, and at Grafton, and from the Mississippi river at Grafton.

On sheet No. 3 there are data for the year 1902. Monthly averages made from analyses of samples of water taken from the Illinois river at Kampsville.

On sheet No. 4 there are monthly averages for the waters of the Illinois river at Grafton, for the year 1899, and for the year 1900, and also for the Mississippi river water at Grafton for the same years, that is, 1899 and 1900.

Upon sheet No. 5 there are given the monthly averages of analyses of samples of water taken from the Illinois river at Kampsville during the years 1897, 1898, 1899 and 1900.

8868 Upon sheet No. 6, similar data for the Illinois river at Kampsville during the year 1901.

On sheet No. 7, monthly averages of analyses of samples of water taken from the Illinois river at Averyville during the years 1897, 1898, 1899 and 1900.

Upon sheet No. 8 monthly averages of analyses of samples of water taken from the Illinois and Michigan canal at Lockport during the year 1901; from the drainage canal at the Bear Trap Dam at Lockport during 1901; from the drainage canal at Joliet east side, during the year 1901.

On sheet No. 9 there are given the monthly averages of analyses of samples of water collected from the Illinois and Michigan canal at Lockport during the years 1897, 1898, 1899 and 1900.

Upon sheet No. 10 there are given the monthly averages of analyses of samples of water collected from the Desplaines river at Joliet during the years 1899 and 1900.

JUDGE SPRINGER: Let these be designated as Defendants' Exhibit C for identification, sheets 1 to 10 inclusive, A. W. P. They are not to be printed in the record but may be at the request of counsel of either side, incorporated in the testimony hereafter, and are to be held by the Commissioner for reference by counsel on either side if they so desire.

8869 MR. JEFFRIES: I object to the introduction of the exhibit in question embodying the ten sheets referred to as tables of averages for the years 1899 to 1900 inclusive, for the reason that the sanitary condition of the water in a running stream is not to be measured by its average chemical condition throughout the period of one year or two years, or one month or six months, and any table of averages of this character fails to disclose conditions of abnormal character which are as important in the determination of the issues involved in this case as conditions at any other period. In fact such conditions so far as the determinations of the sanitary condition of water are concerned, are the all-important conditions to be ascertained and determined, and if it be found from a sanitary standpoint that the water in a running stream is infected at any one time during any twelve months or six months or three months, its character as a suitable water for domestic and drinking purposes is brought in question, and such water could not be safely used for such purposes, and so far as the issues involved in this case are concerned, the defense are called upon to meet such abnormal conditions and not to show that by a general table of averages the condition of the water is less subjected to infected matter on the average than it is at any one given time during the period in question.

8870 Said documents are marked for identification by the Commissicner, as requested.

JUDGE SPRINGER: The objection of counsel goes merely to the weight of the evidence and not to its admissibility. The abnormal conditions if any, to which counsel has referred, will be found in the tables of detailed analyses which have been put in evidence, namely, tables 1 to 80 of this series, and all other tables heretofore read in evidence in this case.

MR. JEFFRIES: As to whether my objection goes to the weight of the testimony is a question for the court, but I now insist that it goes to the materiality and admissibility of the testimony in this, to-wit; that no table of averages can be relied upon by any sanitarian in undertaking to pass judgment upon the sanitary condition of the water in a running stream or in a given quantity of water.

JUDGE SPRINGER: That is a question for the Court to determine.

MR. JEFFRIES: And for this reason the evidence is inadmissible and my objection does not go to the weight of the testimony and the weight of the evidence as shown by the tables, but to its admissibility, because the tables themselves show from what has been stated in the objection, that conditions
8871 there shown are not to be relied upon and not being reliable, consequently are not admissible.

JUDGE SPRINGER: As before stated, these are questions for the Court to consider and counsel for defendants respectfully submit them to the Court.

Q. Professor, have you any data which show the conditions of the water in the Illinois river just prior to the opening of the sanitary canal as to stages of water, temperature, proportions of constituents, etc.

A. I have.

Q. Will you submit that data at this time?

A. The numerical data, that is, the figures resulting from the analytical determinations, have all been introduced in the detailed tables 1 to 80 which have been referred to above,but some of these data, and the data with respect to stages of water and the temperature of the water, I have represented upon plates Nos. XXXIX and XL, heretofore introduced in evidence and to which I now refer in response to the question of counsel, the

Plates being as follows:

Plate XXXIX.—A. W. P.

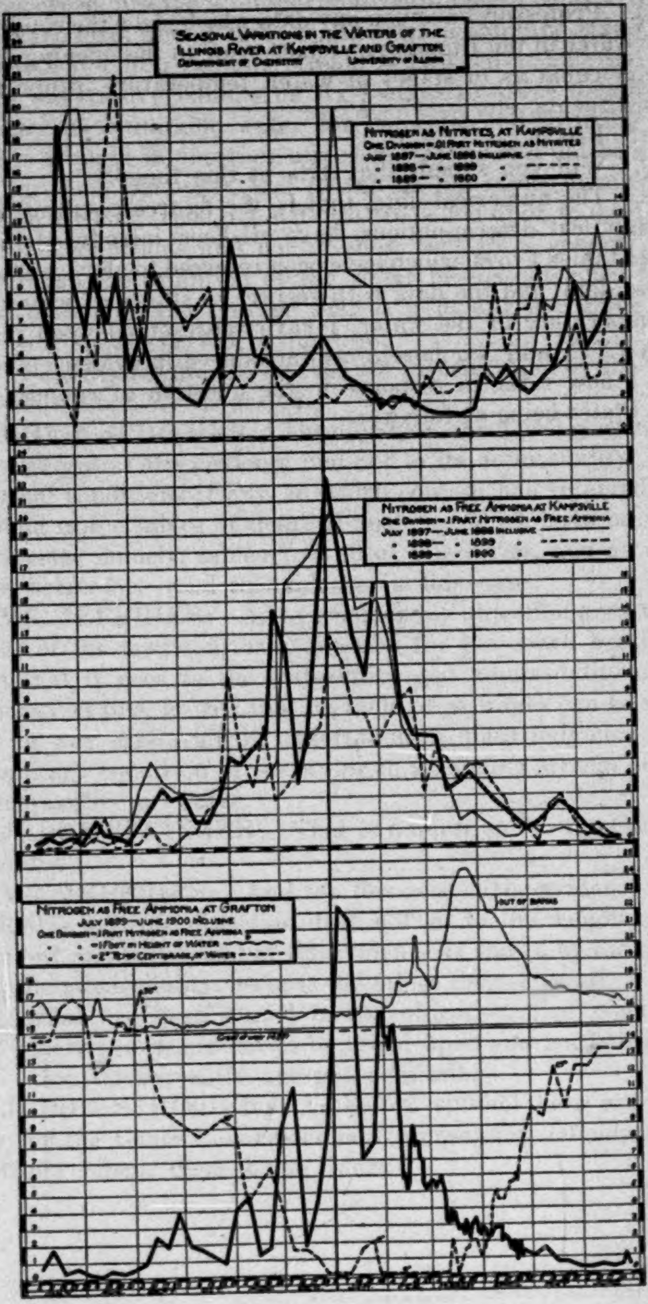

Plate XL.—A. W. P.

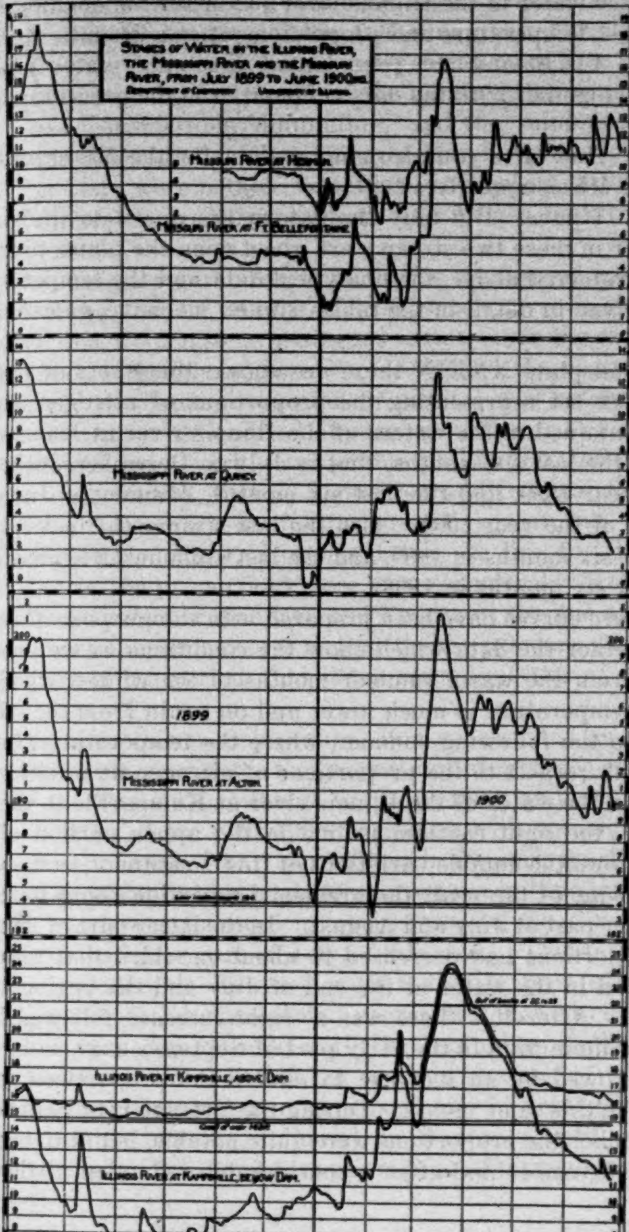

Stages of Water in the Illinois River, the Mississippi River and the Missouri River, from July 1899 to June 1900 inc.
Department of Chemistry
University of Illinois
Missouri River at Hermann
Missouri River at Ft. Bellefontaine
Mississippi River at Quincy
1899
Mississippi River at Alton
1900
Illinois River at Kampsville, above Dam
Illinois River at Kampsville, below Dam

8874 Q. Have you also any data which show the condition of the water in the Illinois river just after the opening as to its stages, temperature and proportions of constituents, etc?

A. I have, and have represented them upon plates XXXIX and XL together with the data referred to in the preceding question.

Q. And have you also similar data for the Missouri river and the Mississippi river?

A. I have. But only the data with respect to the stages of water in these two streams are given upon the plates to which I have referred above, the analytical data and the temperatures being given in detail in the tables 1 to 80 inclusive, above referred to.

Upon plate XXXIX there are shown three sets of curves, the upper set representing the proportions of nitrogen as nitrites contained in the waters of the Illinois river at Kampsville during the last six months, that is July to December, inclusive, of the year 1899, and the first six months, January to June, inclusive, of the year 1900. Also the last six months in 1898 and the first six months in 1899, and the last six months in 1897, and the first six months in 1898.

These curves have been prepared with the purpose of bringing together the data which show the conditions as we proceed from the warm summer months to the winter, when the
8875 temperature is much lower and on again from the winter to the following summer, where the temperature rises.

With respect to the proportions of nitrogen as nitrites contained in the water of the Illinois river at Kampsville in the fall of 1897, the light continuous line in the upper portion of the plate shows the notable variations of this constituent, in the various seasons of the year, the greatest proportion being found in the latter part of July and August. In the latter part of August, the proportions had decreased to about one-third that which is contained in the water at the end of July and the beginning of August. After this there was a slight increase followed by a notable diminution in the early part of September, which in turn was followed by an increase to double the proportions found earlier in this same month. During the latter part of September and October the proportions were quite notable, but at the begining of November and after a considerable reduction at the end

of October, they rise again to considerable proportions, which were practically maintained to the end of the year; that is, until the beginning of January of the following year, namely, 1898. In January they rose very considerably, being more than doubled in proportion in the early part of the month, after which there was considerable diminution, and the minimum point
8876 was reached at the beginning of March, from which time on there were notable variations, but mainly in the direction of increases in the proportions of nitrogen as nitrites, to near the end of the year.

Following the curve for 1898, that is the last six months of 1898, and the first six months of 1899, which curve is shown as a broken line, we find some analagous variations in the early part of the year, although in the end of July and the beginning of August the minimum proportion of nitrites was reached, with the maximum for this period appearing at the end of August; this followed by a very considerable diminution, the line for the next two months, that is, September and October, following almost the same course as for the preceding year, but with the beginning of November, dropping below the line for the other year, that is, the proportions were very considerably less during November, December, January and February, the line again following much the same course as that for the previous year in the latter part of the period, that is the second quarter of the year 1899.

The third line in this group,—that represented as a heavy continuous line, represents the proportions of nitrogen as nitrites during the last six months of the year 1899, and the first six months of the year 1900, beginning with notable propor-
8877 tions namely .1 part per million in the early part of July.

There was a drop to about .05 part per million later in the month, which was followed by an increase to .09 of a part per million in the latter part of July of this year. This followed by a very considerable decrease until the early part of August. In August several increases and decreases followed each other, but none very considerable until the beginning of September, when the proportions diminished to about one-half of what they had been in the latter part of August. Later in September, there was a notable increase, followed by decreases until we get a minimum figure .02 of one part per million of nitrogen as nitrites

in the middle of October. In the latter part of October an increase again, reaching the maximum early in November, reaching .12 of one part of nitrogen as nitrites per million; this followed by decreases until the minimum was found in the latter part of December, after which an increase took place to the first of January following, namely January, 1900, and in the beginning of the year 1900, there was considerable diminution in the proportion of nitrites continuously until the early part of February after which there was a very slight increase in the proportions from .018 of one part per million upon February 7th, to .023
of one part per million on February 14th, to .022 of one
8878 part per million on February 21st, this being followed by
diminutions throughout the month of March. The next increase in proportion of nitrites coming in the early part of April, following after which there were the ordinary increases and decreases in the proportions of nitrites similar in character to those which I have referred to above, as taking place in the previous years here considered.

It is evident from these lines, which merely represent the figures in tables 37 to 41 inclusive, that the proportions of nitrites contained in the waters of the Illinois river as they were about to discharge into the Mississippi river, were not during the early months of the year 1900, that is particularly January, February and March, 1900, abnormal. In fact the proportions were very much less than were found in the waters of the Illinois at this same point during the same months of the year 1898, and while somewhat greater in the first part of January than the proportions found at this point in the year 1899, during the latter part of January and during the month of February the figures were almost identical and beginning with March the proportions were almost uniformly less during the year 1900, until the month of June in the early part of which and in the latter
part of May, the proportions rose somewhat beyond those
8879 which had existed in the water of the Illinois at this
point for this time in the year 1899, but were still less than the proportions which had been found in the water at this point in the preceding year at this time, namely, the year 1898.

The second group, that is the group at the middle of plate XXXIX represents the proportions of nitrogen as free ammonia contained in the water of the Illinois river at Kampsville, for the same periods referred to above in discussion of the nitrites.

The light continuous line represents the proportions of nitrogen as free ammonia contained in the water of the Illinois river at Kampsville during the last six months of 1897, and the first six months that is, January to June inclusive of the year 1898. It is very notable from the curves which merely represent the figures which are given in detail in tables 37 to 41 inclusive above referred to, that the proportions of free ammonia are less in the summer time, the months of July and August, that they begin to increase in September, reaching a considerable proportion about the middle of September, after which they diminish somewhat, but remain of notable proportions without much change either up or down, during the months of October and November, until at the beginning of December there is a very remarkable increase in the proportion of nitro-
8880 gen as free ammonia, as the colder weather of the winter season approaches or arrives.

From the early part of December, when the proportion found was 1.6 parts per million, there is again notable increase in the proportions of the nitrogen as free ammonia, to the early part of January when the proportions were somewhat more than two parts per million, after which there is a slight decrease to nearly the middle of January followed by a more considerable decrease to 1.44 parts per million upon the 18th of January, and increase to 1.5 parts per million upon the first day of February, followed by a decrease to 1.24 parts per million on the 8th, and a further decrease to .72 parts per million on the 15th of February, a still further decrease to .956 parts per million upon the 22nd of February, and further decrease to .52 parts per million upon the first of March, after which there was more continuous and more considerable successive diminutions until the minimum was reached in April, and from that time to the end of June the proportions never rose to as much as .01 of a part of nitrogen as free ammonia per million.

Following the broken line of this set, which represents the proportions of the nitrogen as free ammonia for the late months, that is the last six months of 1898, and for the first six
8881 months of the year 1899, we note that in the latter part of the year there were similar variations to those referred to above, but that the proportions did not increase so early in

the year, that is, the proportions found in the water during September were practically similar to those found in the same water in July and August, but that with the beginning of October considerable increase of the nitrogen as free ammonia took place, the maximum being reached early in November, which was followed by a decrease to the middle of November; this in turn followed by an increase to the latter part of November, the minimum for November being reached at .28 of one part per million upon the 29th. After this there were considerable increases until the maximum proportion of nitrogen as free ammonia for the period now in question was reached, upon January 3rd, 1899, the proportion being 1.28 parts per million. After this there were diminutions in the proportions of nitrogen as free ammonia until at the end of January, namely January 31st, 1899, there were but .6 parts per million, which was followed, however, by increases to a maximum of .96 parts per million of nitrogen as free ammonia, upon February 21st. After this there were successive decreases and increases, but on the whole diminutions until the warm weather of the summer period was reached,
8882 when the proportions were as usual for this season of the
year, less than .1 part per million. Following the heavy continuous line which represents the proportions of nitrogen as free ammonia in the waters of the Illinois river at Kampsville during the last six months of 1899 and the first six months of the year 1900, we find nothing particularly unusual in the proportions of the curve. During the first part of the year the lines follow the course above described for the lines for the same months of 1897 and 1898. In the months of September and October it more nearly corresponds to the curve for the year 1897, showing greater proportions than were found during the year 1898, and proportions somewhat less than the considerable proportions found during these months in the year 1897. About the middle of October there was a decrease of nearly 50 per cent in the proportion of nitrogen as free ammonia, followed by an increase more considerable until the proportions .552 parts per million, upon the first day of November, followed by a slight decrease to the next week, and that in turn by an increase to .688 parts per million on the 22nd, and 1.44 parts per million on the 29th of November, 1899. Following this there was a decrease to 1.184 parts per million upon the 6th of December. A further

diminution to .368 upon the 13th of December, and from that time an increase to .672 parts per million upon the 20th
8883 of December. Following this increase in the latter part of December there was further increase to the maximum of 2.24 parts of nitrogen as free ammonia per million upon the 3rd day of January, 1900; from the 3rd of January, 1900, to the 17th of January the same month, there was a decrease in the proportions of nitrogen as free ammonia contained in the waters of the Illinois river at Kampsville, to 1.28 parts per million, and a further decrease between the 17th of January and the 25th of January. The proportion upon the latter date being 1.04 parts per million. From this date to the 31st of January there is a notable increase in the proportions of nitrogen as free ammonia, the maximum of 1.6 parts per million being reached upon January 31st, the same proportion being found a week later, that is, for February 7th. From which time there was a considerable decrease in the proportions of nitrogen as free ammonia, to .736 parts per million, upon the 14th of February; to .672 parts per million upon the 21st of February; to .656 parts per million upon the 7th of March; again to .32 upon the 14th of March, an increase to .368 parts per million, upon the 21st of March, and again to .432 parts per million upon the 28th of March. From this time on there were variations in both directions, but
8884 the general directon of the curve was in the way to represent the diminutions which are shown in the detailed tables of analyses, as occurring during the warmer summer months.

Comparison of this line representing the conditions with respect to the proportions of nitrogen as free ammonia in the waters of the Illinois river at Kampsville during the last six months of the year 1899 and the first six months of the year 1900, show in general great similarity between the conditions during this period of twelve months and the period of twelve months referred to above, that is, the period July, 1897, to June, 1898, inclusive.

The third group of lines upon this plate gives a representation of the proportions of nitrogen as free ammonia contained in the water of the Illinois river at Grafton thirty miles below the point we have been considering, and within two miles of the point where the discharge of the water from the Illinois into the Mississippi occurs. The heavy continuous line represents the proportions of nitrogen as free ammonia. The broken line represents the temperature of the water as taken at the time the samples for analyses were collected. The upper curve represents the height of water as read at Government gauges at Kampsville. The stages are given for Kampsville because at this point there is ordinarily no disturbances due 8885 to variations in height of the water in the Mississippi river.

At times back water from the Mississippi river causes higher water above the dam at Kampsville, but this is only in times of extreme high water in the Mississippi, while ordinarily at Grafton the stages in the Illinois river follow uniformly the variations in the stages of the Mississippi river.

MR. JEFFRIES: You mean extremely high water in the Mississippi?

A. Yes, sir. The line representing the proportions of nitrogen as free ammonia in this group have been compared from the figures which appear in tables Nos. 21 and 60 of the series 1 to 80 heretofore read in evidence. The data for the latter part of 1899 and for the first part of the month of January, 1900, being thus derived from analyses of collections made once a week, but beginning with the 24th of January the collections were made more frequently and from the 28th of January, 1900, on, the collections were made each day, that is, until the end of April, and the data from these daily collections are represented in the curve for this section of the period in question.

The stages of water represented by the upper curve of this group are the daily readings, or, rather, the mean of tri-daily readings, as in the other case the stages of water and 8886 volume of discharge referred to above in my testimony in discussing the conditions at Kampsville.

In the early part of July, 1899, the nitrogen as free ammonia contained in the waters of the Illinois river at Grafton increased from .06 parts per million on the 5th, to .176 parts per million on the 12th, following which there was a decrease to .03 parts per million upon the 19th, after which the proportions were at the minimum until they began to increase in the early part of September, reaching the proportions .24 parts per million upon the 13th, decreasing to .18, and increasing again to .396 upon

the 27th of September, these increases being followed by a decrease to .192 parts per million upon October 4th, to .172 parts per million October 11th, to .084 parts per million on October 25th. The decreases to this point being followed by a considerable increase to .404 upon the first day of November, to .48 upon the 8th of November, these increases being followed by a considerable drop to .12 parts per million upon the 15th. An increase then occurred to .16 parts per million upon the 22nd, to .88 parts per million upon the 29th, to the maximum of 1.12 upon the 6th of December, the increase being followed by a great decrease to .176 parts per million upon the 13th, which is in turn
followed by an increase to .432 parts per million on the
8887 20th, to .88 parts per million of nitrogen as free ammonia
upon the 27th of December, 1899. The increase in proportions of free ammonia continued. The proportion upon January 4th, 1900, being the maximum for the entire period under consideration, namely, 2.24 parts per million nitrogen as free ammonia.

Slight diminution from the 4th to the 10th occurring, the proportion on the latter date being 2.16 parts per million; after this there was a considerable diminution to .704 parts per million upon the 17th day of January, 1900. After this an increase to .8 parts per million upon the 24th of January to 1.6 parts per million upon the 28th, upon the 29th, upon the 30th and upon the 31st of January; then a decrease to 1.24 parts per million upon the first day of February, 1900, the same proportion being found upon the 2nd of February; upon the 3rd day of February the proportion being 1.36; upon the 4th day of February a slight increase again to 1.44 parts per million, an increase again upon the 5th to 1.504, and again upon the 6th an increase to 1.52 parts per million; after this upon the 7th a diminution to 1.36; upon the 8th to 1.28; upon the 9th to .96; upon the 10th to .72; upon the 11th to .576, followed by an increase upon the 12th to .608, and a decrease upon the 13th to
.512. Again upon the 14th a slight increase to .544, fol-
8888 lowed by a greater increase to .8 parts per million upon
the 15th. Upon the 16th the proportion being the same, that is, .8. After this, an increase upon the 16th and 17th to .896 and a decrease to the 18th to .768. From this point on there were various minor increases and decreases, the general

direction or variation, however, being a diminution toward the minimum, which was reached in the warmer months of the year represented in this period, namely, May and June, for the year 1900. The relation of temperature to the proportion of nitrogen as free ammonia is in part illustrated by the curves in this group, for it is notable that as the temperature diminishes in the autumn months, that is, in September, the nitrogen as free ammonia increases in proportion. In this particular year there was an increase in the temperature of the water in the latter part of October, and in conformity with this there appears, or at least in unison with this there appears a decrease in the proportion of nitrogen as free ammonia; then a considerable fall in temperature of the water in the early part of November was accompanied by an increase in the proportion of free ammonia while the increase in temperature of water later in the month was accompanied by a decrease in the proportion of nitrogen as free ammonia. A very considerable further decrease in temperature during the latter part of November and the early 8889 part of December was followed in the early part of December by a considerable rise in the proportion of free ammonia. Toward the middle of December there was again a very considerable diminution in the proportions of the nitrogen as free ammonia, although at this time the temperature of the water remained constant, or but a very slight increase. No other very general relation between the temperature condition and the proportion of free ammonia for this time appears. A further decrease in the temperature of the water to the freezing point, that is, zero degree centigrade, in the latter part of December was accompanied by a very great increase in the proportions of free ammonia contained in these waters. In the latter part of December and the early part of January, a notable rise in temperature of the water from the freezing point, that is, zero centigrade, to four degrees centigrade, just about the middle of January, which rise in temperature was mainly caused by weather conditions, including the precipitation of rain at this time; these were accompanied by a very considerable diminution in the proportions of nitrogen as free ammonia.

Following this [illegible]e was again a drop in the temperature of the water to the freezing point, that is, zero degrees centi-

grade, which was accompanied by another very con-
8890 siderable rise in the proportions of nitrogen as free ammonia and later, although the temperature remained practically the same, that is, zero centigrade, there was a considerable diminution in proportions of free ammonia in the waters of the Illinois at this point which was coincident with a very considerable rise in the stage of water in the river and the volume of flow at this time, which increased very considerably as shown in the various plates upon which the discharges of the Illinois river over the Kampsville dam, have been represented.

From the early part of March on, the temperature of the water was gradually rising until the maximum was reached. Of course in the warm summer months, and step by step with this rise in temperature, there were notable diminutions in the proportions of free ammonia, but the very great diminution in the proportions of free ammonia in February and through March, 1900, corresponded throughout with the diminutions and other variations referred to above in our discussion, and the variations of nitrogen as free ammonia in the waters of the Illinois at Kampsville, and were in part occasioned by the high water naturally produced by precipitation as rain during the latter part of February and March and the early part of April during the year 1900.

MR. JEFFRIES: After having examined Defendants'
8891 Exhibit C for identification composed of sheets 1 to 10, inclusive, I move to strike it out for the reason that the table of averages for the year 1901 and for the other years therein contained is in part upon the result of the analysis of one sample of water or one collection of water, while other parts are based upon averages for 12 and 6 months, and various other periods of time. I move to strike out the exhibit for the reason that the data contained in them are not competent and do not correctly represent the table of averages for the various rivers and at the various places in such a manner as to be comparable.

JUDGE SPRINGER: This objection goes merely to the weight of the evidence. The table shows for itself, what it is.

Q. Professor, what were the relative stages of water in the Illinois, Mississippi and Missouri rivers late in 1899 and early in the year 1900?

A. As I have represented upon plate XL refered to above, the stages of water in the Missouri river, the Mississippi river and the Illinois river were in the latter part of the year 1899 comparatively low, but in the Missouri river at Fort Bellefontaine and in the Mississippi river at Quincy and at Alton the water was remarkably low just at the end of the year 1899, that is, after having been in general low throughout the
8892 later months of the year, that is, throughout the months
of October, November and December, there was a very considerable fall in the stage of water in these streams just at the end of December, and in some cases, continuing into the early part of January following, that is, January of the year 1900. After this there was a very considerable increase in the height of the water in the Mississippi river both at Quincy and at Alton and in the Missouri river both at Fort Bellefontaine and at Hermann; Hermann being some considerable distance higher up the Missouri river where but little effect of the height of the water in the Mississippi river would ordinarily be felt, and Quincy being more than 100 miles farther up the Mississippi river than is Alton and where no effect upon the height of the water in the Mississippi caused by high stages or low stages in the water of the Missouri river would ordinarily be felt.

I have put in this curve for Quincy and the section of a curve for Hermann in order to show that the conditions at Alton for the Mississippi river and at Fort Bellefontaine for the Missouri river were not caused in the one river by the conditions in the other particularly, but that they existed also at points considerably farther up each of these streams respectively.

8893 In January, the latter part, it is notable that the Missouri went from a little less—it is notable that the Missouri at Fort Bellefontaine rose from a little less than two feet upon the gauge, to seven feet, a rise of five feet between the early part of the month and the latter part, while the Mississippi river at Quincy also rose from the end of December, being less than one foot upon the gauge—it rose to a little more than three feet upon the gauge at Quincy in the early part of January, to be followed by a decrease to two feet a little later, and in the latter part of January rising to 3.6 feet. This followed by a decrease to a little less than two feet in the early part of February, an increase from less than two feet to more than five feet, and a rise of over three feet in the stage of water in the river at this point. Later in this month, that is, February, during the middle, the rise came, the stage of water reached six feet, to be followed by a decrease, that is, a fall in the water to about three feet in the end of the month, but in the early part of March there was a sudden and great increase in the height of the water at Quincy, to approximately 13 feet.

The stages of water in the Mississippi at Alton follow the same general course as indicated by the curve, but were more considerable both in the rise and in the fall. In
8894 the end of December, 1899, the water in the Mississippi river at Alton reached the extreme low water stage. From there it rose to three feet in the early part of January following to February but rising again in the latter part of January to more than nine feet upon the guage. From this date to the early part of February there was a very considerable fall in the stages of the water at this point. It went below the extreme low water point but was almost immediately followed by a rise of more than six feet. From this time on there were minor variations in height, the maximum being reached in the latter part of February, followed by a decrease in the early part of March which in turn was followed by a very considerable rise in the stage of the water a little later in March from which time there was a more or less continuous diminution to the end of the period, covered by this plate.

The lines representing the stages of water in the Mississippi river at Alton follow much the same general direction and in general are much similar in proportion to those representing the stages at Quincy, but the rises at this point are more considerable, and the falls in stage of water also more considerable, that is, the variations up and down are more notable at Alton than at Quincy and conform more nearly to the variations both
8895 up and down as shown for the Missouri river at Fort Bellefontaine and at Hermann, than they do with the upper Mississippi at Quincy.

The lower set of curves upon this plate No. XL, represent the stages of water above and below the dam at Kampsville, the crest of the dam being at 14.8 feet upon the government gauge, from which the readings are taken at this point.

A curve representing the stages of water below the dam shows the variations which are in part occasioned by the relative stages of water in the Mississippi, in the vicinity of the mouth of the Illinois, while the curves representing the stages of water above the dam vary somewhat in conformity with these. They are not so much and ordinarily in fact are not at all particularly affected by the stages of water in the Mississippi.

On the upper part of this section of the curve a cross line drawn at the horizontal line marked 22 in the scale at the side, indicates a point at which the water in the Illinois river at Kampsville above the dam begins to go over the banks. It is between stage 22 and 23 feet. The fact that the length of time in the year when such conditions as send the water over the banks and in part around the dam prevail, is short, is apparent by comparison of that section of the curve represented
8896 by the line 22 feet, with the date scale at the bottom of the set of curves.

Adjourned until 2:00 p. m., same day, Wednesday, November 18th, 1903.

8897 2:00 p. m., Wednesday, November 18th, 1903. Continuation pursuant to adjournment.

Present, the Commissioner and same counsel representing the respective parties.

PROF. ARTHUR W. PALMER,

resumed the stand for further direct-examination, by Judge Springer, and testified as follows:

Q. Professor, at the time of the noon recess you had just completed your statement in regard to the stages of water in the Illinois, the Missisippi and the Missouri rivers late in the years 1899 and early in 1900. What effect did these conditions and changes have upon the condition of the waters of each of these streams?

A. The conditions of the water of the Illinois river at Kampsville and at Grafton at this time, and the relation of these conditions to the stage of water in the Illinois river have been discussed somewhat in detail in my testimony of this morning and also incidentally in my testimony with respect to the water at Kampsville and at Grafton given yesterday, and illustrated or rather represented graphically by plates Nos. XII, XIII, 8898 XIV, XV, XVI, XVII, XVIII, XIX, XX, XXI, and XXXIX. The data of the tables series A. W. P., 1 to 80, inclusive, which have been used in preparation of the plates above referred to show that the waters of the Illinois during the first three months of the year 1900, that is, January, February and March, 1900, were in practically the same condition as they ordinarily are in this season of the year as shown by comparison of the data of analyses of the waters collected during these three months of the year 1900, with the data of analyses of samples of water collected at the same points in the Illinois river during the same months of the years 1897, 1898 and 1899.

With respect to the waters of the Mississippi river at this time I would refer to my testimony and discussion of the data of analyses of samples of water drawn from the Mississippi river at Quincy and at Grafton above the mouth of the Illinois river during this period, namely, the months of January, February and March, 1900, and given in the respective tables of series A. W. P., 1 to 80, inclusive, and represented for purposes of illustration and ready comprehension in part in charts XXII, XXIII, XXIV, XXV, XXXIII and XXXIV, respectively.

8899 Consideration of the data of the tables referred to shows that early in January of the year 1900, nitrogen as albuminoid ammonia and the total organic nitrogen were present in the waters of the Mississippi at this point, Grafton, in about the same proportions as in the waters of the Illinois, and that in the middle of February, there was a very considerable increase in the proportions of total organic nitrogen as of nitrogen as albuminoid ammonia in the waters of the Mississippi river above the mouth of the Illinois, which increase in these substances was fully as great in the waters of the Mississippi as in the waters of the Illinois river, and was doubtless occasioned by causes similar to those which at this time brought about these increases in the waters of the Illinois, namely, a rise of notable proportions in the height of water in the stream following upon an unusual fall in the stage of water which in turn had followed a somewhat lengthy period of comparatively low water.

The conditions in the Missouri river as stated in my testimony regarding the stages of water in that stream at the same

time that I discussed the stages in the Illinois and Mississippi were with respect to variations in height of water in the stream similar in character and in extent to those in the Missis-
8900 sippi and similar in character but greater in proportion than those in the Illinois river.

The determinations of the total organic nitrogen and nitrogen as albuminoid ammonia in the samples of water collected from the Missouri river at Fort Bellefontaine show that the variations in height of water in that stream were accompanied by similar variations in the proportions of these constituents of the waters, that is, there was a very considerable increase in the proportions of nitrogenous organic matters contained in the waters of the Missouri river just at this time, the latter part of January and the early part of February, of the year 1900.

While my data with respect to the composition of the waters of the Missouri river at this time are not as numerous as those which I have described concerning the composition and the constituents contained in the waters of the Mississippi and the Illinois, the results of these analyses show similar fluctuations and by reference to the data submitted in this case on behalf of the complainant in the case, that is, the tables of results of chemical analyses of waters of the Missouri river made by Professor Teichmann, we find that his results fully corroborate my own with respect to these conditions in the Missouri river water, and being more numerous than my own, having been taken
8901 daily in the Missouri river, afford a series of determinations which compared from day to day with those which I obtained for the Illinois and the Mississippi rivers, and show even more conclusively than do my own, more meagre data, for this period, a more considerable conformity between the conditions of the water in the Missouri river and the Mississippi river at this time, that is, the complainant's data for this period show a worse condition in this respect in the waters of the Missouri river at Fort Bellefontaine than do my own less numerous data, for the reason that they cover the period more fully and they show complete conformity with the conditions I have stated with respect to the Mississippi river; the data with respect to the free ammonia in the waters of these streams my own for the three rivers, and as corroboative of my data for the Missouri river, and refers to the data already referred to, presented by the

complainant, these show similar conditions, that is, similar fluctuations and increase in the proportion of free ammonia contained in the water of each one of these three streams at the time I have mentioned, that is, coincident with the rises in the height of water in these three streams and particularly in the Missouri and in the Mississippi above the mouth of the Illinois during the early part of February and March, 1900.

8902 Q. What effect did these conditions have upon these waters at the St. Louis intake in so far as these rivers respectively contribute such waters?

A. These conditions involving as they do an increase in the proportions of the various nitrogenous organic matters in the waters of the upper Mississippi and in the waters of the Missouri river, and the increased proportions of these substances and matters which accompany them in the mixture of waters passing down the Mississippi river below the mouth of the Missouri increase them in that mixture, which is drawn into the St. Louis waterworks system at the intake tower at the chain of rocks.

Q. Have the waters in the lower reaches of the Illinois river been more greatly charged with organic matters since the opening of the Chicago drainage canal than they were prior to the opening of the canal?

MR. JEFFRIES: We object to the question for the reason that it is not a question as to whether or not they have been more greatly charged. The question is whether or not it is charged with organic matter coming from the city of Chicago. The question is not whether or not the drainage canal discharges more water into the Mississippi river, but whether or not it discharges more of its sewage or whether or not its sewage 8903 is discharged into the Mississippi river at Grafton by means of the Illinois river, and it matters not whether it be accompanied by a large volume of water or a small volume of water. The question is as to the quantity of pollution and infected material discharged into the Illinois river and thence into the Missisippi.

Q. (Question repeated.)

A. They have not. The data to which I have testified and the various plates representing different portions of the data particularly those referring to the condition of the water in the

Illinois river at Kampsville and at Grafton and testified to somewhat in detail heretofore by me, show that the water in the lower reaches of the Illinois river is now, since the opening of the Chicago main drainage channel, less charged with organic matters than it was previous to that opening.

Q. Have you prepared any data from samples of water taken at cross-sections of the Illinois and Mississippi rivers which you have not heretofore put in evidence? If so, will you please produce them?

A. I have.

Q. Will you please produce them?

A. I will (witness hands papers to counsel).

Q. Will you please describe these data?

8904 A. I present four sheets. On sheet No. 1 there are special cross-sections taken in the Illinois river at Averyville, upon July 21, 1899, and upon November 26, 1901, cross-sections at Wesley City taken July 22, 1899; cross-section at Peoria at the foot of terminal bridge, taken November 26, 1901, and cross-sections one and one-half miles below Pekin taken November 26th, 1901. These do not involve complete analyses in any one case. In the first case mentioned, namely, Averyville, determinations of the chlorine, of the oxygen consumed by dissolved substances; of the free ammonia and the total albuminoid ammonia and the nitrites and the nitrates were made.

Those taken at Averyville in November, 1901, were subjected to determinations of chlorine merely.

Those taken at Wesley City July 21, 1899, were submitted to determinations for chlorine, free ammonia, total albuminoid ammonia, nitrites and nitrates.

The samples collected by the terminal bridge at Peoria and below Pekin were submitted to determinations of chlorine merely.

These cross-sections were taken for the purpose of noting what if any variations there were in the proportions of constituents contained in the waters at these several points in
8905 the Illinois river at different distances across the stream.

Sheet No. 2 represents the results of analyses of special cross-section samples collected in the Mississippi river at Grafton just above the mouth of the Illinois. Samples collected January 5th, 1897, January 18th, 19, February 15, 1899, May 24, 1899, and July 28, 1899, and also cross-section samples collected in the Illinois river at Grafton January 5th, 1899, and July 28, 1899. Most of these samples were subjected to complete sanitary chemical analyses, such as I have testified to heretofore, with respect to the bulk of the work in this investigation. In a few of these samples a fewer number of determinations were made, as is represented upon the sheet here submitted.

Sheet No. 3 has upon it the results of analyses of samples collected at certain cross-sections of the Mississippi river at Hartford, within half a mile of the mouth of the Missouri river, a portion of these samples were subjected to complete sanitary chemical analyses. In another portion of them only the chlorine was determined, and in yet another the chlorine and the nitrogen as nitrites were determined. At the bottom of this sheet No. 3 there are several analyses of samples of water collected below the mouth of the Missouri river at different points across the Mississippi within two miles of the mouth of the Missouri, and one sample collected a quarter of a mile within the mouth of the Missouri river. 8906

Sheet No. 4 of this series contains the results of analyses of special cross-section samples collected in the Mississippi river at Alton and at points below Alton, namely, at Hartford, and at the chain of rocks opposite the intake tower of the St. Louis waterworks.

JUDGE SPRINGER: I now offer these tables in evidence in this case.

MR. JEFFRIES: I object to the reading of the data in evidence for the reason that as witness has stated, they do not contain a complete chemical analysis of the water with reference to the ascertainment of all of the chemical constituents of that water, and as the witness has frequently observed, and as was stated by defendants' witness, Professor Long, that no showing could be made that would or could be relied upon by taking one chemical constituent or ingredient of the water, but that it was necessary to consider all of the chemical constituents of the water with reference to determining the sanitary character of the water under consideration, and that in view of these facts and of the position that the defense has taken with reference to testimony of this character I object to this data being read in evi-

dence because of its being incomplete and not sufficient,
8907 and such data as may appear would at the most be misleading, uncertain and therefore incompetent and irrelevant.

JUDGE SPRINGER: Counsel for defendants suggest that these tables do not purport to state other facts than those shown upon their face; that they are to be considered in connection with all the other data submitted in evidence in this case; that we are making an earnest effort to bring into the case all the data that it is possible to collect.

MR. JEFFRIES: In addition to the objection above stated, I object to the reading of the data in evidence for the further reason that the chemical ascertainments shown therein are not of such character as would be comparable, or is comparable with any other facts introduced in evidence by this witness or by any witness on the part of the defense, and not being comparable it is incompetent and irrelevant to consider them along with the other facts shown in evidence by the defense.

JUDGE SPRIIGER: Counsel for defendants further suggests that both of these objections go to the weight of the testimony and not to its competency, and are more of an argument than they are objections.

MR. JEFFRIES: My objection goes to the competency and not to the weight.

JUDGE SPRINGER: Your objection goes, as you stated, to the competency, but as counsel for defendants insists,
8908 it relates only to the weight of the evidence and as to which is right upon this is a matter to be determined by the Court.

MR. JEFFRIES: It is to be determined by the Court as to whether it goes to the weight or the competency of the evidence, but I submit, however, that it goes to the competency of the evidence itself.

JUDGE SPRINGER: The tables are as follows, and are to be known as Defendants' Special Cross-Sections Numbered 1 to 4, A. W. P., inclusive.

THE WITNESS: The tables are as follows:

3909 DEFENDANTS' SPECIAL CROSS-SECTIONS, NO. 1.

DEPARTMENT OF CHEMISTRY, UNIVERSITY OF ILLINOIS.

SANITARY WATER ANALYSIS.—PARTS PER MILLION.—ARTHUR W. PALMER.

8913 Q. Professor, will you now explain the significance of these ascertainments?

MR. JEFFRIES: I object to any explanation of the significance of the ascertainments contained in the defendants' special cross-sections, A. W. P., 1 to 4, inclusive, for the reasons stated in my objection to their being read in evidence.

A. The data of the special cross-sections made at Averyville show that the waters of the Illinois river are of substantially the same composition, that is, contain substantially the same proportions of chlorine and of other constituents at various points across the stream; that the entire body of water passing this point, in the Illinois river is substantially homogeneous as regards those substances, generally determined in the sanitary chemical analyses of waters.

The chlorine determinations alone is sufficient to show the substantial uniformity of composition of the water at the different points in the cross-section, hence the different points across the stream.

The purpose of making such cross-section determinations lies in the fact that when different bodies of water are brought together into one stream, it takes some considerable time for
them to mingle completely, and our data show what has
8914 repeatedly been referred to in giving my testimony, that
at different points in the various streams considered in this investigation the waters from different sources do not mingle completely, so that analyses of samples taken at one point in the stream at such a place would not fairly represent the composition of the entire body of water passing down that stream opposite said point.

The data with respect to the cross-section samples at Averyville show that by the time the waters of the Illinois river containing the discharges from the Illinois and Michigan canal from the Chicago main drainage channel; from the upper Desplaines river, the Kankakee river, the Fox river and numerous other minor tributary streams and containing sewage discharges from various towns situated upon its banks, have by the time they reach Averyville completely commingled so that the waters passing this point at the Narrows at Averyville, is of uniform homogeneous character, with respect to the constituents referred to.

The cross-section at Wesley City, made in July, 1899, in-

volving a determination of chlorine, of free ammonia, of total albuminoid ammonia, of nitrites and nitrates, show that the water at this point is not uniform in character all the way across the stream so far as various significanct chemical
8915 constituents are concerned. The differences in proportions of chlorine at different points here are not great, but the differences in the proportions of nitrogen as free ammonia are very considerable between the two sides of the stream.

The free ammonia at the east shore at this point was but .256 parts per million, while at the west shore within five feet of the west shore the proportion was 2.24 parts per million of nitrogen as free ammonia. At the other points in the cross-section, namely, one-third distance and two-thirds distance across the stream the proportions of nitrogen as free ammonia were greater than near the east shore, but nowhere near so great as the proportions found close to the west shore of the river at this point. This excess of free ammonia near the west shore of the stream at Wesley City is derived from or was at that time, derived from the discharges of Peoria sewage, including industrial wastes and house sewage, distillery slop, cattle shed slop, refuse and so on, passing down mainly along the west bank of the river at this point, so that the condition of the water at the west bank at Wesley City is in these respects far inferior to its condition near the east bank, that is, for the time specified,—July, 1899.

The determinations made near the terminal bridge at Peoria and below Pekin, which determinations involve merely the chlorine, show somewhat notable though not considerable
8916 variations in the proportions of chlorine at the cross-section points; the greater proportion of chlorine being found near the west shore; the smaller proportion being found near the east shore.

On sheet No. 2, defendants' special cross-sections, No. 2, the cross-section samples collected from the Mississippi river just above the mouth of the Illinois at Grafton, were taken for the purpose of determining whether the waters of the Mississippi at this point were substantially of uniform composition across the stream, and it was found that they were, that there were no very notable differences in the composition at the different points in the cross-section,—the cross-section samples being taken at various intervals, ranging from January, 1899, to July 28th, 1899.

Cross-sections taken in the Illinois river at Grafton January 5th, 1899, and July 28th, 1899, show substantial uniformity of the composition of the waters of the Illinois at different points across the stream.

Defendants' Special Cross-section Sheet No. 3, containing data of the analyses of cross-section samples collected in the Mississippi river at Hartford half a mile above the mouth of the Missouri river, which samples were collected December 6th, 1899, and July 7th, 1900, and August 17th, 1900, show 8917 that the waters of the Mississippi river have not commingled perfectly with the waters of the Illinois river by the time these two bodies of water have reached this point where they are about to come in contact with the waters of the Missouri river, and show that even down to this point the waters of the Illinois river pass down mainly along the Illinois shore, while the water passing down near to the Missouri shore is mainly the water of the upper Mississippi river.

The cross-section of the Mississippi river taken two miles below the mouth of the Missouri river merely afford evidence of the incomplete commingling of the three bodies of water at this point, and is corroborative of the more extensive series of cross-section analyses which have heretofore been testified to.

Defendants' Special Cross-section Analyses Sheet No. 4 contains the results of analyses of samples of water collected in special cross-sections at Alton, Hartford and at the chain of rocks. These samples having been collected at the same cross-section points referred to above, but in addition to the ordinary collection, collections were made at different depths below the surface, for the purpose of determining whether the composition at a given point was the same at different depths below the surface of the water in the river.

8918 They show in general that there was at times considerable difference between the proportions of constituents found in the water at eighteen inches below the surface and at depths from six to ten and up to 30 feet below the surface at points where the water reached such depths.

Q. Professor, have you made any special collections in reference to these waters which are not already put in evidence in this case? If so, please state what they are?

A. Oh, yes, I have made a great many special collections of data with regard to water. I have got everything that is published so far as I know and have studied it at various times.

Q. Have you any of that data with you that you could put in evidence?

A. I have not.

Q. Have you made any special collections of waters from these rivers which you have not given in evidence?

A. I have made a few other special collections of waters. I have not got all the data for them here. I made one series of cross-section collections for determinations of chlorine at La Salle during the summer of 1899, which showed that at this point at that particular time, the water at different points across the Illinois river beside the wagon bridge at LaSalle, was of substantially uniform composition all the way across the 8919 stream.

I made also special collections of water from the Illinois river at Grafton for the purpose of noting whether the composition varied at different times in the day, that is, during the 24 hours, and I have that data here on sheet No. 5, Special Collections.

Q. Will you explain that sheet, please?

A. This sheet contains the results of analyses of samples of water collected during 24 hours from the Illinois river at Havana on June 23rd, and 24th, 1899. Again similar collections made November 1st and 2nd, 1899, and similar 24 hour collections of water from the Illinois river at Havana, November 1st and 2nd, 1897, and August 5th and 6th, 1898.

JUDGE SPRINGER: I now offer this sheet in evidence, to be known as Defendants' Special 24 hour collections No. 1, A. W. P.

MR. JEFFRIES: I object to it for the reason that the analyses of water in the Illinois river prior to the opening of the canal, there is no evidence showing the manner and the time it was taken, and for the further reason, that the cause of the chemical changes in the condition of the water as stated by the witness yesterday afternoon with reference to certain ingredients is misleading and indefinite, and does not correctly represent the condition of the water in the river at the time the samples

8920 were taken, and at no time during the date the samples were taken.

8922 Q. Now, you may explain this further, Professor, if you will ?

A. For the purpose of noting whether the composition of the water in the Illinois river varied greatly during the 24 hours on November 1st and 2nd, 1897, samples of water were collected from the Illinois river at Havana, at a point a short distance above the mouth of the Spoon river and Quiver lake, during both the day and the night. Samples taken from the river every two hours during this time were mixed together, thus yielding a composite sample representing the character of the water during the 24 hours covered by these collections, and the data secured by the analysis of said sample given in this table No. 2, Defendants' Special 24 Hour Collection, A. W. P., show that the composition of the water collected in this manner is substantially the same as that of samples collected upon previous days, for the same period and upon days shortly following those indicating that the ordinary collection of a single sample yields results which are substantially correct for the composition of the water passing during at least the 24 hours in which the period of collection ordinarily falls.

Q. In other words, that the effect of the darkness is not substantially manifest in the ascertainments?

A. So far as chemical contents determined in the sani-
8923 tary chemical analyses of the water is concerned.

Q. State under what circumstances these collections of water were taken. Under what authority?

A. They were taken under my direction and in my presence. I helped but did not do all the work in this particular case.

MR. JEFFRIES: Do you mean to say you sat up for 24 hours?

A. I have done that more than once.

JUDGE SPRINGER: I want to get in what capacity you were acting at the time?

A. As professor of chemistry of the University of Illinois in charge of the chemical survey of the waters of the state of Illinois with which duty I have been charged by the president and trusees of the university, and acting under the provisions of the act of the Legislature before cited in this case.

Q. Were these analyses made at the time the samples were taken or near that time?

A. They were made immediately afterward; they were sent to the laboratory as have been other samples collected, concerning which I have testified.

Q. They were taken then in pursuance of your official duties three years before the pending suit was brought?

A. They were.

Q. Will you please continue your explanation of this plate, Professor?

8924 A. Upon August 5th and 6th, 1898, another similar collection was made at the same point, at Havana, and gave results which were simply corroboative of those referred to above regarding the sample collected at this point November 1st and 2nd, 1897.

On June 23rd and 24th, 1899, some similar 24 hour collections were made in the Illinois river at Grafton. The collection at this time and place, however, was made under somewhat different circumstances by means of a specially constructed galvanized iron boat or tank; the samples were collected continuously during the 24 hours, that is, every hour, every minute and every second of the 24 hours. By means of siphon tube connections the water was kept continuously flowing throughout the 24 hours into the sample bottle into which it was taken for shipment to the laboratory and subsequent analysis. At this time but two samples were taken at the same point simultaneously, one eighteen inches below the surface of the stream and the other eighteen feet below the surface of the stream, or about two feet above the bottom, the water at this point at this time in the Illinois river being about twenty feet in depth. These two analyses compared with other analyses of samples collected at about the same time at this point show substantial uniformity therewith, and comparison of the two 24 hour collections made simultaneously here shows substantial uniformity of the composition of the water at this point throughout the depth 8925 of the stream. The chlorines were identical in proportion; the oxygen consumed was somewhat greater in the sample collected near the surface, than it was in the sample collected near the bottom of the river. The free ammonia was precisely the same in both samples, as was also the total albuminoid ammonia, though the dissolved albuminoid ammonia, that is, albuminoid ammonia derived from dissolved substances, was somewhat greater in the water collected at the depth of eighteen feet than it was in the sample collected at the depth of eighteen inches, the suspended matters being greater in the water near the surface at this time.

Total organic nitrogen was found to be slightly more considerable in proportions in the water taken near the surface than in the water taken near the bottom.

The dissolved total organic nitrogen being somewhat greater at the greater depth, and less near the surface; the suspended matters conversely being greatest near the surface and least near the bottom.

Nitrites were .017 parts per million in the sample taken at eighteen inches below the surface, and were .022 parts per million in the sample taken at 18 feet beneath the surface, while the nitrates were the same,—1.12 in each case.

MR. JEFFRIES: At what point was that, professor?

8926 A. This was the Illinois river at Grafton, in 1899, June 23rd and 24th, 1899.

8927 Q. Were any samples of water taken from the rivers in question in the latter part of the year 1901?

A. There were.

Q. Will you please explain the circumstances under which they were taken?

A. In 1901 a series of examinations of water at points in the Illinois river, the Mississippi river and the Missouri river were made by me on behalf of the Sanitary District of Chicago.

J. Have you the detailed examinations of those waters?

A. I have; they are here upon these sheets.

Q. Please state briefly what these sheets contain so as to advise counsel of their contents.

A. They contain analyses of samples of water collected from the Illinois river at Averyville during October, November and December, 1901. Analyses of samples of water collected from the Illinois river at Pekin for the same months, 1901; collected in the Illinois river at Grafton, October, November and December, 1901. The Mississippi river at Grafton, October, November and December, 1901; the Missouri river at Fort Bellefontaine, October, November and December, 1901; the Mississippi river at the chain of rocks, the Illinois shore, at the mid-channel,

at the intake tower, and near the Missouri show all during
8928 the months of October, November and December, 1901.

Q. Will you explain the circumstances under which those were taken and in what manner they were taken?

A. They were taken in the manner hereinbefore testified to, by various collectors who have been on the stand as witnesses in this case and in accordance with the same directions to which they have testified, the collectors having made out certificates upon the same blanks as those already testified to. In fact the certificates of these analyses I believe are in the possession of the Court together with those covering earlier periods of the investigation, namely the periods from May, to December, 1899, and from January to October, inclusive, 1900.

Q. How many samples in all have you taken?

A. I have not counted them; a good many.

Q. When were those analyses made?

A. These analyses were made by me in the same laboratory as that before referred to, the University of Illinois, at Champaign.

JUDGE SPRINGER: I offer these tables in evidence to be known as Sanitary District series 1901, A. W. P. Sheets numbers 1 to 21 inclusive.

The tables are as follows:

8929

CHEMICAL ANALYSIS.

8950 Q. Professor, will you please explain these tables in detail?

A. Sheets Nos. 1 and 2 contain the results of analyses of 65 samples of water collected from the Illinois river at Averyville, during the period October 1st to December 30th, 1901. Some of the samples were subjected to the ordinary complete sanitary chemical analysis. In a portion of them only the chlorine was determined and from lack of time we made no attempt to determine other constituents, in the samples collected each day. Only the samples collected on alternate days were submitted to complete sanitary chemical analysis.

Sheets 3 and 4 contain results of analyses of 62 samples of water collected from the Illinois river at Pekin covering the period October 15th to December 28th, 1901. In this case as in the case of Averyville only half of the samples, that is, those collected on alternate days were subjected to the complete sanitary chemical analyses, the others having merely the chlorine determination.

Sheets 5 and 6 contain the results of the analyses of samples of water collected from the Illinois river at Grafton, covering the period October 2nd to December 23rd inclusive, in all 62 samples.

8951 Sheets 7 and 8 contain the results of analyses of samples collected during the same period upon the same dates but from the Mississippi river at Grafton just above the mouth of the Illinois.

Sheets 9 and 10 contain the results of the analyses of samples of water collected from the Missouri river at Fort Bellefontaine, 53 samples in all collected, during the period October 11th to December 16th, 1901, inclusive.

Sheets 11 and 12 contain the results of analyses of samples of water collected from the Mississippi river at the chain of rocks near the Illinois shore at the point referred to in the testimony given concerning the earlier series of chemical examination. In all there were fifty samples of water taken at this point and subjected to chemical analyses, the results of these appearing upon these sheets Nos. 11 and 12.

Sheets Nos. 13 and 14 contain the results of analyses of samples of water collected at the chain of rocks, but at mid-channel in the Mississippi river, 51 samples in all covering the period October 3rd to December 14th inclusive, 1901.

Sheets 15 and 16 contain results of analyses of samples of water collected at the chain of rocks taken from the Mississippi river beside the intake tower of the St. Louis waterworks, 51 samples in number, covering the period October 3rd, to December 14th, 1901.

8952 Sheets 17 and 18 contain the results of analyses of samples of water collected from the Mississippi river at the chain of rocks but near the Missouri shore, 51 samples in all covering the period October 3rd to December 14th inclusive, 1901.

Sheets Nos. 19 and 20 contain the averages of the analyses just referred to; the averages for each month, that is, October, November and December, for each point, and the general average for the entire three months period.

Q. Professor, have you prepared any plates graphically illustrating the detailed examinations contained in these tables?

A. I have.

Q. Will you produce them?

A. They are here.

Q. Will you please explain what those plates indicate or show?

A. Plate No. 101, series 1901, A. W. P., represents the averages for the period of three months, October, November and December, 1901, and those for the same three months in 1899 in parallel columns.

The comparison of the three rivers, the Missouri, the Mississippi and the Illinois, exhibits a very great difference between the Illinois and the Missouri on one hand and the Mississippi on the other, during the periods in question.

8953 This plate represents the average proportions of chlorine in the waters of the Illinois river at Grafton, the Mississippi river at Grafton above the mouth of the Illinois, the Missouri river at Fort Bellefontaine and at four points in a cross-section at the chain of rocks, for the months of October, November and December, 1899 and the same months in 1901.

The comparison of the three rivers, that is the Illinois just above its mouth at Grafton, the Mississippi just above the mouth of the Illinois at Grafton and the Missouri river at Fort Bellefontaine, exhibit a very great difference between the Illinois and the Missouri on the one hand and the Mississippi on the other, during the periods in question.

The content of chlorine in the Mississippi is practically the same as in the earlier year, the same in 1901 as in the earlier years.

The content of chlorine in the Mississippi river water was about the same as in the Illinois river. The greater dilution in 1901 has of course manifested itself in somewhat lower chlorine than in the year 1899.

The significance of these features is determined upon the fact that we have demonstrated elsewhere that the water
8954 of the Illinois river does not mix perfectly with the water
of the Mississippi on its way from Grafton down to the chain of rocks, and that the Illinois river water flows mainly close to the Illinois shore, while the water near the Missouri shore consists mainly of Mississippi river water, mixed only slightly with Illinois river water, though at mid-channel there is more or less considerable mixing of the waters of the two streams. That these conditions prevail down to the mouth of the Missouri river, the Missouri river water as it enters the Mississippi deflects the Mississippi river water forcing it toward the Illinois shore, and it passes down chiefly toward the Missouri shore. It mixes of course to some extent with the fluid coming down from the upper Mississippi at this point, but it is substantially but slightly mixed Mississippi river water, which is toward the Missouri shore; that is the main body of water from the Illinois river is toward the Illinois shore and it is water of the Mississippi river mixed with but small proportions of the water from the Illinois, which comes into immediate contact with the discharge from the Missouri river when the Missouri river water enters the bed of the Mississippi and it is quite unlikely that any considerable proportion of Illinois river water mixes at first with the Missouri river water, but rather it is mainly Mississippi river water containing but a small proportion of the water
8955 of the Illinois river.

What we have then, briefly stated is, first, a body of Missouri river water passes down the west or Missouri bank; second, the mixture of Mississippi river water with Missouri river water, containing but a very slight proportion of Illinois river water; third, Mississippi river water containing more Illinois river water in the middle; fourth, Mississippi river water mixed with a more considerable proportion of the water of the Illinois river; fifth, near the Illinois shore the larger proportion of Illinois river water mixes of course with the Mississippi river water and to some extent also with the water of the Missouri river.

To be sure, there is no fixed line of demarkation between any of these mixtures, but the mixing takes place gradually, and we certainly have combinations such as I have indicated at the different points across stream. Water for samples taken at the chain of rocks shows that the water at the Illinois shore contains far less chlorine than does the Illinois river water pure and simple, but far more than does the Mississippi river water above Grafton. There has occurred a somewhat extensive mixing at mid-stream. We find water having almost the same content of chlorine as at the Illinois shore, while at the intake there
is less chlorine than in the Missouri river water at Fort
8956 Bellefontaine and considerably less than at the Missouri
shore. It is to be noted, however, that the collections at
Fort Bellefontaine are not quite so numerous as those at the chain of rocks. They did not begin for some ten days or so after the time when those taken at the chain of rocks began.

The data of the analyses show, and it is evident from the relative heights of these columns that although the Missouri river water did not extend so far across the stream beyond the intake tower in 1901 as it did in 1899, yet, there was no more Mississippi river water and there was no more Illinois river water in the mixture at the intake tower in 1901, that is, after the opening of the Chicago main drainage channel, than there was in 1899.

Upon chart 102 of this series there are represented the proportions of oxygen consumed or required by the waters of the Illinois river at Grafton, the Mississippi river at Grafton just above the mouth of the Illinois; the Missouri river at Bellefontaine just above its mouth and the Mississippi river at four different points across the stream opposite the St. Louis waterworks intake at the chain of rocks.

The columns representing general averages of analyses of
samples collected during three months, October, Novem-
8957 ber and December 1901 and the same three months for
the year 1899.

A comparison of the three rivers shows at once that the total oxygen required was much greater in the Mississippi river water than in the Illinois and was still greater in the Missouri river water than in the Mississippi.

It shows further that the oxygen required by matters in solution in the water, was much greater in the Mississippi water than in the water of the Illinois, and less in the Missouri river water than either the water of the Illinois or the Mississippi. In this respect the Mississippi river water was inferior to both the Illinois river water and the Missouri river water. A cross-section at the chain of rocks shows that in 1901 there was a greater difference between the two sides of the river and particularly between the waters passing down the side of the intake tower and that passing down along the Illinois shore than in 1899.

Comparison of the three rivers shows too a considerable improvement in the Illinois river in 1901 as compared with its condition in 1899, and an improvement too, in the Mississippi river in 1901 as compared with its condition during the same period of 1899.

8958 While the conditions in the Missouri river were worse during this period in 1901 than they were in the same period in 1899.

ADJOURNED until 10:00 A. M. following day, Thursday, November 19th, 1903.

10:00 A. M., Thursday, November 19, 1903.

8959 Continuation pursuant to adjournment.

Present, the Commissioner and same counsel representing the respective parties.

PROF. ARTHUR W. PALMER,

resumed the stand for further direct-examination by Judge Springer and testified as follows:

Q. Professor, at the adjournment on yesterday afternoon you were considering certain charts based upon the tables of chemical analyses of waters taken from the Illinois and Missouri rivers in the months of October, November and December, 1901, and you had explained the graphic illustrations on chart 102, and had concluded your consideration of that chart. Will you proceed with the other charts based upon those tables?

A. I will. At first I would like to turn over the sheet of averages mentioned yesterday which when the rest of the tables of figures relating to the work of 1901 were introduced, was found to be missing. I found it this morning, and it will be numbered Sanitary District Series 1901, A. W. P. 21.

8960 Q. You may now proceed with your explanation of chart 103.

A. Chart No. 103 of this series represents the average proportions of nitrogen as albuminoid ammonia contained in the waters of the Illinois river at Grafton, the Mississippi river at Grafton just above the mouth of the Illinois, the Missouri river at Fort Bellefontaine, just above its mouth, and at four different points across the stream of the Mississippi river at the St. Louis waterworks intake at Chain of Docks. Data from which these averages represented upon the charts are made, which averages are upon sheet 21 of the series, covering the three months, October, November and December, 1899 and 1901.

The conditions with respect to the proportions of albuminoid nitrogen as revealed by this chart is somewhat similar to those exhibited by chart 102, representing the proportions of oxygen required; that is, the total albuminoid oxygen was greater in proportion in the Missouri river water in 1901 than in either the Mississipi or the Illinois, while the albuminoid nitrogen in solution was less in the Missouri than in the others.

In 1889 the conditions in these respects were much worse than in 1901, although in the Illinois river, and in the Mississippi river, and the cross section at the chain of rocks,
8961 there is shown much less mixing of the water of the Mississippi river with that of the Missouri at the intake tower during the autumn of 1901, than existed in the corresponding season of 1899.

Chart No. 104 of this series represents the total solids, both mineral and organic matters in the waters of the Illinois river at Grafton, the Mississippi at Grafton just above the mouth of the Illinois; the Missouri river at Fort Bellefontaine, and so on, the same points as referred to in the three preceding charts of this series, and is based upon similar averages covering the two periods of three months each, namely October, November and December, 1899 and October, November and December, 1901.

Comparison of the three rivers shows that the total solids in the Illinois river water were notably less in proportion in 1901 than in 1899, and the same is true concerning the water of the Mississippi river. On the other hand the water of the Missouri contained considerably more total solids in 1901, than it did in 1899, the mineral matters in solution too, are very much

greater in quantity in the Missouri river water than in the Mississippi river water, and are notably greater than in the Illinois river water, but the greatest difference between the
8962 Missouri river water on one hand, and the Mississippi and Illinois on the other, is in the proportions of suspended matters, the suspended matters in the Missouri river water during this period in 1899 amounted to about 448 parts per million, while during the season of 1901 they amounted to 906 parts per million. During the same periods the proportions of suspended matters in the Illinois river averaged about 42 parts per million for both years.

In the Missisippi river water in 1899 there were about 55 parts of suspended matters per million. In 1901 about 32 parts per million. It would seem that during these periods the averages representing the quantities of matters in suspension constitute the best basis for calculation of the relative proportions of water from the three streams contained in the mixture at the points where the three have more or less come together.

A comparison of the data at the chain of rocks where we note the relative quantities of the suspended matters at the four different points across the stream, shows at once that there is far less mixing of the Illinois river water with that of the Mississippi and that of the Mississippi with the Missouri in 1901, that is after the opening of the Chicago main drainage channel, than there was in 1899, the season just preceding the
8963 opening of the drainage channel. The relative proportions of suspended matters contained in these waters at the several different points across the stream at the chain of rocks and also in the three different rivers are shown more in detail upon chart 105, that is upon this chart, instead of having the averages for the entire period represented by columns, there are lines, that is, curves, which represent the proportions contained in the water on the day of each collection. The very notable increase in suspended matters in the Illinois river, December 16th, 1901 appears to be due to the fact that the Mississippi and Missouri rivers fell greatly and suddenly at this time, and created a rapid current in the lower Illinois, that is, particularly between the Kampsville dam and Grafton, thus causing a scouring out of the Illinois river along this stretch. The conditions which prevailed during the same season in 1899 are exhibited upon chart No. 106.

Comparison of the two charts shows how much greater were the differences between the Missouri river water on the one hand and the Illinois and Mississipi river water on the other and how much less complete was the mixing of these waters at the chain of rocks in 1901 than it was in the corresponding season of 1899.

The total solids in suspension are shown in detail upon 8964 chart No. 107 of this series, and this again exhibits the great difference between the water at the intake tower and that passing down near the Illinois shore, and also shows that there is comparatively little mixing even so far across the stream as the mid-channel of the Mississippi river; that is a point somewhat to the east of the intake tower.

The fact that the water at the Missouri shore itself frequently contains less suspended matters than that at the intake tower is undoubtedly due to the fact that in times of low water the main current is further out from the shore and beside the intake tower, while the water nearer to the Missouri shore flowing with less velocity does not retain so much matter in suspension as does that farther out, which is moving more swiftly.

The solid matters in solution both at the different points at the chain of rocks and in the three separate rivers, are shown upon chart No. 108. The features exhibited with this chart show again that between the mixture of the Illinois river water and the Mississippi river water, which is passing along the Illinois shore, and the Mississippi river water which hugs the Missouri shore, is a body of water consisting chiefly of upper Mississippi river water which intervenes between that coming down the Illinois shore and the body of water passing 8965 down beside the intake tower, and the Missouri shore, and substantially prevents the Illinois river water from reaching the body of water which enters the intake of the St. Louis waterworks.

The relative quantities of total solid matters that is both the matters in solution and those in suspension, contained in the waters of the different streams are shown on chart No. 109, which simply corroborates what has been stated above respecting the significance of the lines of charts 107 and 108, and the others of this series.

JUDGE SPRINGER: I now offer these charts in evidence as Defendants' Exhibits 5, 6, 7, 8, 9, 10, 11, 12 and 13.

Said charts received in evidence and so marked by the Commissioner.

(Charts not reproduced in print.)

Q. Professor, have the proportions of organic matters in the Illinois river near the mouth been greater or less since January, 1900?

A. They have been less.

Q. Have you any data bearing upon that that you have not presented?

A. Yes, or rather I have it in the form different from that
in which it has already been presented. It has gone in
8966 the detailed tables 1 to 80 inclusive, which we have been
discussing, and it was incidentally contained in the tables
of monthly averages which were introduced yesterday.

I now have in hand certain tables which bring together the averages of the different constituents for the different years in order to facilitate a ready comparison, a comparison which may indeed be made by study of the detailed tables or by study of the tables of monthly averages, but which being here brought together are more easily considered, and their significance more easily grasped.

Q. In what shape is that data?

A. Well, I have it in the form of tables here, typewritten tables much of it; some of it I have only in my original personal note-book.

Q. Well, will you explain those tables and those data?

A. I will. The tables are designated Combined monthly and yearly averages of proportions of certain chemical constituents of the waters of the Illinois river at Kampsville, and are numbered from 1 to 7.

8967 Q. Now professor, will you explain these tables?

A. Table No. 1 of this series gives the proportions of total organic nitrogen as determined by the Kjel Dahl process in the water of the Illinois river at Kampsville during the years 1897, 1898, 1899, 1900, 1901 and 1902, both for the monthly averages and the yearly averages. These represent the monthly averages of anlyses for each year during the period, and the yearly average has been made from all of the detailed analyses made during the year.

The averages for the entire years 1897, 1898 and 1899 have been combined into an average for the three year period, and also the yearly averages for 1900, 1901 and 1902, have been combined into an average for that three year period. The three years average prior to 1900 is 1.0866 parts per million of total

organic nitrogen, and for the three years subsequent to the opening of the Chicago main drainage channel, that is, for the three years 1900, 1901 and 1902; the composite average is .8966. Calculating the percentage difference between these two averages, it appears that there has been a decrease in the proportions of total organic nitrogen in the waters of the Illinois river since the opening of the Chicago drainage channel, amounting to 17.48 per cent. Direct determinations of the total
organic nitrogen were discontinued after September,
8968 1901, and from that time on to the end of 1902, the data
which appear in these tables have been calculated from
the relation between the proportions of nitrogen as total organic nitrogen and nitrogen as albuminoid ammonia, on the basis of the nitrogen as albuminoid ammonia, constituting forty per cent. of the total organic nitrogen.

Table No. 1 is as follows:

8969 PROPORTIONS OF TOTAL ORGANIC NITROGEN IN THE WATER OF THE ILLINOIS RIVER. KAMPSVILLE. MONTHLY AVERAGES.

	1897	1898	1899	1900	1901	1902

Per cent. decrease 17.48.

8970 Upon table No. 2 of this series there is shown similar averages both monthly and yearly, for the dissolved organic nitrogen, that is, the total organic nitrogen held in solution or contained in substances which are in solution in the water. The general averages for the three year periods are given at the bottom; they are .636 for the period 1897 to 1899 inclusive, and .522 for the period 1900 to 1902, inclusive. The percentage difference between these is 17.92 which shows a decrease in the proportions of the organic nitrogen derived from dissolved substances, since the opening of the Chicago main drainage channel, of 17.92 per cent.

Table No. 2 is as follows:

8971 PROPORTIONS OF DISSOLVED ORGANIC NITROGEN IN THE WATER OF THE ILLINOIS RIVER.

KAMPSVILLE—MONTHLY AVERAGES

	1897	1898	1899	1900	1901

Decrease 17.92.

8972 Table No. 3 of this series gives in similar way the monthly averages and yearly averages of proportions of nitrogen as albuminoid ammonia, for the years 1897 to 1902 inclusive, and at the bottom of the sheet there are given also the averages for the first six months and the averages for the second six months. In addition, at the bottom there is given the general average for the three years period, 1897 to 1899 inclusive, and the three year period, 1900 to 1902, inclusive, that is for the three years immediately preceding the opening of the Chicago main drainage channel and the three years immediately following the opening. The general average for the earlier period is .4665 parts per million; for the period immediately following the opening it is .3495. The difference between these two amounts to 25 per cent, showing that the decrease in the proportions of nitrogen as albuminoid ammonia, immediately following and for the three years period subsequent to the opening of the Chicago main drainage channel, is 25 per cent.

Table No. 3 is as follows:

8973 QUANTITIES OF NITROGEN IN THE WATER OF THE ILLINOIS RIVER. TONS DISCHARGED PER 24 HOURS; Calculated from monthly averages of flows and constituents.

Albuminoid Nitrogen; Kampsville.

8974 Table No. 4 of this series represents similar facts. The data with respect to the nitrogen as free ammonia in the waters of the Illinois river at Kampsville, that is, the average monthly proportions and the yearly averages for the years 1897 to 1902 inclusive, and contains also the general averages for each of these three year periods, the average for the three years prior to the opening of the Chicago main drainage channel, was .3717; for the three years period subsequent to the opening of the Chicago main drainage channel, the average was .3957, the relation of these to each other being such as to show an increase in the proportions of nitrogen as free ammonia, of six per cent.

Table No. 4 is as follows:

8975 PROPORTIONS OF NITROGEN AS FREE AMMONIA IN THE WATER OF THE ILLINOIS RIVER, KAMPSVILLE MONTHLY AVERAGES.

8976 Table No. 5 of this series gives similar data with respect to the nitrogen as nitrites contained in the waters of the Illinois river at Kampsville, for the years 1897 to 1902 inclusive, both the monthly averages, the yearly averages and the general averages for the three years period prior to and the three years period subsequent to the opening of the Chicago main drainage channel.

The average for the former period is .0672, and for the latter period is .0405, manifesting thus, the fact that there was a decrease of 40 per cent in the proportions of nitrogen as nitrites contained in the waters of the Illinois river at Kampsville on the average for the three years period subsequent to the opening of the Chicago main drainage channel from the proportions contained on the average during the three years period prior to that opening.

Table No. 5 is as follows:

8977 PROPORTIONS OF NITROGEN AS NITRITES IN THE WATER OF THE ILLINOIS RIVER, KAMPSVILLE; TOTAL AVERAGES.

Decrease 40 per cent.

8978 Table No. 6 represents by means of monthly averages and yearly averages as in the other tables of this series, the proportions of nitrogen as nitrates, contained in the water of the Illinois river at Kampsville during the years 1897 to 1902 inclusive. There are given also the general averages for the three year period prior to the opening of the Chicago main drainage channel ,and for the three year period subsequent thereto. The relation of these general averages is such as to show an increase in the proportions of nitrogen as nitrates subsequent to the opening of the Chicago main drainage channel of 15 two-thirds per cent.

Table No. 6 is as follows:

8979 PROPORTIONS OF NITROGEN AS NITRATES IN THE WATER OF THE ILLINOIS RIVER, KAMPSVILLE MONTHLY AVERAGES.

8980 Table No. 7 represents the monthly averages of proportions of suspended albuminoid ammonia, that is albuminoid ammonia derived from suspended matters contained in the waters of the Illinois river at Kampsville for the years 1897, 1898 and 1899,and for the years 1900, 1901 and 1902.

The table is as follows:

	1897	1898	1899	1900	1901	1902
January	.349	.4	.28	.26	.256	.244
February,	.244	.31	.266	.272	.24	.224
March,	.214	.32	.304	.2	.296	.246
April,	.209	.32	.294	.208	.22	.26
May,	.288	.344	.251	.232	.245	.216
June,	.36	.253	.264	.216	.234	.28
July,	.345	.275	.216	.176	.223	.277
August,	.296	.274	.181	.179	.224	.224
September,	.363	.23	.264	.208	.169	.192
October,	.36	.196	.268	.164	.179	.203
November,	.292	.206	.267	.212	.16	.186
December	.35	.238	.234	.2	.188	.192
For the year	.3032	.2781	.257	.208	.215	.23

The general average for the three year period before the opening of the main drainage channel is .2794, and for the
three year period subsequent thereto, was .2265, showing
8981 a decrease in the proportions of nitrogen as albuminoid
ammonia derived from suspended matters, of 19 per cent.

Q. Profesor, are the quantities of organic matters in the Chicago sewage discharged into the Desplaines river less or greater since the opening of the Chicago drainage canal than prior thereto.

MR. JEFFRIES: I object to the question for the reason that the witness is not a sanitarian; he has not shown in evidence that he has ever examined the chemical constituents in sewage of any city, or is acquainted with the situation at Chicago either prior to or subsequent to the opening of the drainage canal, or that embodied in the extent of the sewage discharged into the river, or the condition of that sewage.

JUDGE SPRINGER: I submit that a sanitarian would be poorly equipped for his business unless he had taken lessons from a chemist such as Professor Palmer; that the persons who instruct sanitarians ought to be able to know what sanitation is.

MR. JEFFRIES: I suggest in answer to counsel's statement that before the evidence of the existence of the stream can be submitted, that the source must first be established or ascertained.

JUDGE SPRINGER: Proceed, professor.

A. What is the question please?

Q. (Question read).

8982 MR. JEFFRIES: I object to the question for the further reason that it is indefinite.

JUDGE SPRINGER: Perhaps the answer will be a little more definite than the question. It is not intended that the question should suggest all that the witness should state in reference to it.

MR. JEFFRIES: I object to the witness stating anything that will not be responsive to it.

JUDGE SPRINGER: Proceed.

A. They are greater since the opening of the Chicago main drainage channel than they were prior to that opening.

Q. Have you any data bearing upon that point?

A. I have.

Q. Will you produce the data please?

A. I will.

Q. What data have you bearing upon that subject?

A. My data touching this question bears reference chiefly to the quantities of nitrogen in the form of free ammonia and nitrogen held in organic combination, and determined by the Kjel Dahl process, in the waters of the Illinois and Michigan Canal at Lockport, for the years 1896 to 1902 inclusive, and for the waters of the Chicago main drainage channel for the years 1900 and 1901.

8983 The analytical data of defendants' table of Averages No. 1, heretofore introduced in evidence, show that the average proportion of nitrogen as free ammonia in the waters of the Illinois and Michigan canal at Lockport for the four years 1896 to 1899 inclusive, was 13.5 parts per million, and the total organic nitrogen determined by the Kjel Dahl process was 5.3 parts per million.

The average volume pumped into the canal, which was 36,000 cubic feet per minute during these four years, amounts to 1,623,000 tons of water or sewage every 24 hours, which gives us the factor 1.623 for calculating the total weight of nitrogen carried in the canal.

Q. Which canal was this?

A. The Illinois and Michigan canal at Lockport.

We thus find that the discharge of nitrogen as ammonia, that is 13.5 times 1.623 was 21.9 tons per day, that is per 24 hours, and the total organic nitrogen, 5.3 times 1.623, equal to 8.6 tons of total organic nitrogen per day, the sum being 30.5 tons of total nitrogen, that is nitrogen in the form of free ammonia, and nitrogen in organic combination as determined by the Kjel Dahl process. .

I have left out of account the very minute quantities of nitrogen as nitrates for the reason that these are forms of nitrogen in combination with oxygen and hence not regarded
8984 as so nearly allied to organic substances as is the nitrogen as free or saline ammonia. The 8.6 tons of total organic nitrogen represents 53.75 tons of protein or nitrogenous organic matters, and the 21.9 tons of nitrogen as free ammonia if presumed to have been originally in the form of protein or albuminoid matters, would represent 136.9 tons of nitrogenous organic matters. Upon this basis the total quantities of nitrogenous organic matters discharged through the Illinois and Michigan canal, before the opening of the Chicago main drainage channel would amount to 190.7 tons per 24 hours.

It is probable that the population contributing to the sewage which flows into the Chicago river, and was transferred from the Chicago river to the Illinois and Michigan canal during the period in question, excreted 34 tons of urea per 24 hours, corresponding to 15.7 tons of nitrogen, and that the major part of the 21.9 tons of nitrogen as free ammonia contained in the water of the Illinois and Michigan Canal was derived from this source, and not from the more complex nitrogenous organic matters or proteid bodies. The quantities of organic matters contained in the waters of the canal however, were undoubtedly far less than the total quantities of these matters discharged into the river by the proportion of the population considered, the difference being in very large measure, due to the putrefica-
8985 tive changes which begin in the sewers and proceed actively in the river. The changes which formerly oc-

curred in the waters of the Chicago river were similar in most respects to those which take place in the so-called septic tanks, and which serve to destroy much of the organic matter, some of it being converted into comparatively inoffensive sludge, and another portion into gaseous substances which partly escape into the air, some of them characterized by disagreeable odors, but others, as free ammonia, carbon dioxide, nitrogen, hydrogen, and so on, being comparatively inoffensive. The fact that ordinarily there was but very slight difference between the quantities of these matters contained in the water of the canal at Lockport, and the quantities contained at Bridgeport, which has been shown by the comparative analyses of samples collected at these two different points, one at the beginning of the Illinois and Michigan canal at Bridgeport in Chicago; the other at Lockport, the point now under consideration, would appear to indicate that the putrefactive or septic changes which went on in the river proceeded approximately as far as under these conditions it was possible that they should go, and that the matters remaining in the waters of the canal were in a proper condition for the speedy reception of those changes which 8986 mark the next step in the oxidation of the nitrogenous organic matters and their transformation into inocuous products, that is to say, putrefactive changes appear to have approached completion and the conditions become such that no further changes took place, revealed within the canal itself; but the next succeeding step in oxidation and putrefication was facilitated by dilution, of the sewage, and also by introduction of bacterial forms of a different character, derived from or contained in the diluting waters of streams tributary to the Desplaines and the Illinois, or in the waters of the upper Desplaines when these waters were sufficient in volume to have marked diluting effect upon the concentrated, but ripened sewage discharged from the canal into the Desplaines river at Lockport in the main, but in particular at Joliet, three to four miles below.

Since the opening of the sanitary canal of Chicago,—or the main drainage channel, the larger part of Chicago sewage experiences its initial dilution in the Chicago river and passes through the main drainage channel in which the mean daily flow for 1900 was 188,340; for 1901, was 241,323, and for 1902 was 257,006 cubic feet per minute.

The volume of sewage pumped into the Illinois and Michigan Canal which is now intended to subserve purposes of 8987 navigation only, or for purposes of navigation and to supply hydraulic power to the Norton mills at Lockport, was reduced from the former average of 36,000 cubic feet per minute, to 26,700 cubic feet per minute in the year 1900, and to about 23,000 cubic feet per minute during the seven months, May to November, inclusive, in the year 1901; the pumps at Bridgeport standing inoperative during the other months of the year 1901,—the daily and weekly variations in flow of the Illinois and Michigan canal and of the Chicago main drainage channel, as also the daily flow of the upper Desplaines river, measured at Riverside, are shown in plates which have been introduced in evidence.

Throughout 1900 and during such part of 1901 as the pumps were in operation, the Illinois and Michigan canal discharged from 40 to 45 per cent of the nitrogen contained in that part of Chicago's sewage which is conveyed into the Desplaines river, and thence into the Illinois river; the other 55 to 60 per cent during this period passing through the main drainage channel.

That the disposition, that is, the destruction of the organic matters of the sewage by the natural proceses which are in operation in the waters of the sanitary canal, the Des- 8988 plaines river and the Illinois river, are facilitated by the increased dilution affected by the operation of the Chicago main drainage channel, has been demonstrated by the investigation of the waters of the Illinois river at Averyville and Kampsville as heretofore testified to by me.

The data in the following tables have been calculated from the average daily flows for each month, in each canal, and the monthly averages of the analytical data.

Q. Will you put those tables in evidence at this time?

A. Yes sir.

These tables are known as Quantities of nitrogen as free ammonia, and total organic nitrogen, in the Chicago sewage discharged into the Desplaines river, being numbered 1, 2 and 3, and I will put them in as we reach them.

Q. Now professor, will you please explain these three
8989 tables?

MR. JEFFRIES: I object to the introduction of the tables in evidence, or to their being read in evidence, for the reason that the defendants have not as yet shown the average flow of the Illinois and Michigan Canal in 1896 and 1899 or the mean flow, or even shown in evidence the daily flow, weekly or monthly flows of said canal, facts which are material to the proper interpretation of the tables and essential for the purposes of forming a basis for the introduction of this character of testimony, and for the further reason that the tables do not disclose the maximum and minimum flows of the water throughout said canal during the time mentioned in the tables.

JUDGE SPRINGER: The witness may produce as he proceeds, such data as he has, from which these tables have been prepared, and I desire to suggest that a portion of this information has already been put in in the plates heretofore read in evidence.

MR. JEFFRIES: And were put in subject to my objection that there was no evidence disclosed by the plates and charts to show that they were accurate.

JUDGE SPRINGER: You may proceed and produce such of that data as you have, in your explanation of these
8990 tables?

A. Concerning the flow in the Illinois and Michigan canal during the four years prior to the opening of the Chicago main drainage channel there is no detailed evidence, but the engineers of the Chicago Sanitary District and the engineer to the State Board of Health and others who have studied the question, have given as the mean daily flow, during these years, the volume of 36,000 cubic feet per minute. For the year 1900 the flow has been computed by the engineers of the Sanitary District of Chicago, and are printed in the report of streams examinations, which has been discussed in the conduct of the case now being tried.

From the data contained in that publication which has been furnished to me in duplicate by the engineers of the Board, I have computed the monthly average or the mean daily flow for each month in the year 1900, and these are as follows:

January,	35,156	cubic feet per minute,
February,	38,104	do.
March,	37,326	do.
April,	31,921	do.
May,	28,740	do.
June,	23,188	do.
July,	25,616	do.
August,	23,730	do.
8991 September,	25,977	do.
October,	24,060	do.
November,	22,521	do.
December,	13,778	do.

The mean for the year being 26,768 cubic feet per minute.

From these I have calculated the flow in tons, and give data in units of one million tons per 24 hours. These data are as follows:

January, 1.582, which signifies that there were 1,582,000 tons of sewage, or water pumped into the Illinois and Michigan Canal at Bridgeport, on the average for each 24 hours during the month of January, 1900.

February,	1.71468
March,	1.68
April,	1.4364
May,	1.2933
June,	1.0345
July,	1.1527
August,	1.06785
September,	1.168
October,	1.0827
November,	1.013445
December,	.62

8992 From these data as to the flow in weight of water, the unit is 1,000,000 tons of water or sewage or mixture per 24 hours.

ADJOURNED until 2:00 P. M. same day, Thursday, November 19th, 1903.

2:00 P. M., Thursday, November 19, 1903.

8993 Continuation pursuant to adjournment.

Present, the Commissioner and same counsel representing the respective parties.

PROF. ARTHUR W. PALMER,

resumed the stand for further direct-examination by Judge Springer and testified as follows:

Q. Will you proceed, professor, with the matter under consideration at the time of recess?

A. There was no flow in the Illinois and Michigan canal, that is the pumps at Bridgeport were not in operation until the end of April in the year 1901, and the amount pumped during the months of May, June, July, August, September, October and November are as follows:

May,	23,000	cubic feet per minute,
June,	23,000	do.
July,	23,000	do.
August,	23,300	do.
September,	24,000	do.
October,	24,500	do.
November,	20,100	do.

8994 December there was no pumping done; there was nothing discharged.

Calculated into tons per 24 hours and units of one million tons, these are, for

May,	1.035
June,	1.035
July,	1.035
August,	1.0485
September,	1.05
October,	1.1
November,	.9045

The average for the period of seven months being 1.034.

The flow in the drainage canal, that is the discharge at 8995 the Bear Trap Dam during the year 1901, the mean per 24 hours for each of the twelve months, was as follows:

Month.	Cubic feet per minute.	Tons per 24 hours in units of one million.
January,	295,000	13.27
February,	304,800	13.7
March,	317,700	14.3
April,	275,000	12.37
May,	190,000	8.55
June,	175,000	7.87
July,	180,000	8.1
August,	236,000	10.6
September,	234,000	10.53
October,	230,000	10.35
November,	234,000	10.53
December,	246,000	11.07
Mean for the year,	242,000	10.89

8996 The flow in the Chicago main drainage channel for the year 1900, that is the mean flow per 24 hours for each month and the tons of discharge in units per million, are as follows:

January,	179,682	8.08
February,	138,834	6.36
March,	125,935	5.66
April,	106,644	7.36
May,	161,400	7.46
June,	193,542	8.71
July,	203,447	9.155
August,	224,256	10.19
September,	138,417	6.21
October,	171,490	7.717
November,	228,775	10.3
December,	254,900	11.47

I haven't got the year's average stated here, but I have it somewhere else. I can easily supply that. We will not wait for it now.

Q. Professor, you will now proceed with the explanation of table 1 heretofore referred to and put in evidence?

8997 A. Table No. 1 shows the discharge of nitrogen as free ammonia from the Illinois and Michigan canal and the

Chicago main drainage channel, or sanitary canal, in tons per 24 hours, during each of the months of the year 1900, and the year 1901, the figures in the column opposite each month representing the mean discharge of nitrogen as free ammonia for each 24 hours throughout the month represented. There is shown also the mean discharge in tons per 24 hours for the year both from the Illinois and Michigan canal and from the sanitary canal or drainage channel, and the sum of these, which represents the total amount of nitrogen in the form of free ammonia contained in the sewage discharged by means of these two canals from Chicago or by Chicago into the Desplaines, and thence into the Illinois river, the mean flow in cubic feet per minute for the Illinois and Michigan canal for the year 1900 is stated at the bottom of the column designated "I. & M." The mean daily flow or discharge from the sanitary canal for the year is stated at the bottom of the column designated "Sanitary" for 1900, and is 188,340 cubic feet per minute.

The fourth column in this table contains the sum of the nitrogen as free ammonia discharged by the Illinois and Michigan canal and that discharged by the main drainage
8998 channel or sanitary canal.

The fifth column in this table contains the figures showing the quantities of nitrogen as free ammonia discharged by the Illinois and Michigan canal during the year 1900.

It will be noted that during the first four months nothing appears in this column for the reason that there was no discharge, the pumps at Bridgeport being left inactive during this time, and again during the month of December, the blank is present for the reason that there was no pumping and no discharge from this canal during the month of December, 1901.

The figures for the sixth column represent the quantities in tons per 24 hours of nitrogen as free ammonia discharged by the sanitary canal and in the 7th column there appears the sum of the nitrogen as free ammonia discharged by the Illinois and Michigan canal and by the sanitary canal for each month during the year 1901. The figures in this column representing the total discharge per 24 hours of nitrogen in the form of free or saline ammonia in the Chicago sewage sent through these two canals into the Desplaines and thence into

the Illinois river; the mean flow for the seven months of 1901 during which there was a discharge from the Illinois and Michigan canal, was 23,000 cubic feet per minute; the mean
8999 daily discharge from the sanitary canal during this year being 242,323 cubic feet per minute.

The average flow of the Illinois and Michigan canal during the years 1896 to 1899 is given as 36,000 cubic feet per minute. Upon this basis calculations from the figures representing the average content of nitrogen as free ammonia in the waters of the Illinois and Michigan Canal at Lockport during the years 1896 to 1899 inclusive, which appear in defendants' table of Averages No. 1 A. W. P., show that the average discharge of nitrogen as free ammonia in the Chicago sewage sent into the Desplaines river during the years 1896 to 1899 inclusive, was 21.9 tons per 24 hours and that during the year 1899 the year immediately preceding the opening of the Chicago drainage channel the quantity of nitrogen as saline or free ammonia thus discharged into the Desplaines river in Chicago sewage was 22.5 tons per 24 hours.

The nitrogen as free ammonia represented in the table, that is, for the discharge by the sanitary canal, .2 of one ton per 24 hours, was contained in the diluting lake water drawn through the Chicago river, and not in the sewage discharged into the Chicago river.

9000 Table No. 1 is as follows.

No. 1. A. W. P.

TABLE XXII.

QUANTITIES OF NITROGEN DISCHARGED INTO THE ILLINOIS RIVER IN CHICAGO SEWAGE. NITROGEN AS FREE AMMONIA DISCHARGED IN THE WATER OF THE ILLINOIS AND MICHIGAN CANAL AND THE SANITARY CANAL. TONS PER 24 HOURS.

Average Illinois and Michigan Canal, 1899—22.5. } Mean flow 36,000 cu. ft. min.

Of the Nitrogen as free Ammonia above, .2 ton per 24 hours was contained in the diluting Lake water drawn through the Chicago river.

9001 Table No. 2 of this series, has like data with respect to the total organic nitrogen discharged in Chicago's sewage into the Desplaines and thence into the Illinois river. The data with respect to flows is not repeated here because it is the same as that given in my testimony concerning table No. 1.

In column No. 2 there are given the numbers of tons of nitrogen and organic combination as determined by the Kjel Dahl process contained in the waters discharged each 24 hours during the twelve months of the year 1900.

In the third column is given the number of tons per 24 hours discharged in the waters passing through the main drainage channel, and in the 4th column there is given the sum of the quantities represented in columns 2 and 3, which sum represents the number of tons of nitrogen in organic combination contained in all of the sewage of Chicago which is discharged into the Desplaines river and thence into the Illinois for each 24 hours in each of the months respectively.

In column 5 there is given like data for the Illinois and Michigan canal for the year 1901. Here again the blanks indicate the time when there was no discharge through this canal.

9002 In column 6, there is given similar data respecting the number of tons of total organic nitrogen per 24 hours discharged through the main drainage channel or sanitary canal; and in the 7th column of this table there is shown the sum of the quantities stated in tons, of total organic nitrogen discharged in the Chicago sewage by means of the Illinois and Michigan canal and the main drainage channel, into the Desplaines and thence into the Illinois.

For comparison I have placed at the bottom of the table a statement representing the average for the Illinois and Michigan canal for the years 1896 to 1899 inclusive, the analytical data coming from table No. 1, Defendants Averages and the flow being that stated in table No. 1, or rather the flows per month being those given in my testimony heretofore.

The average for the Illinois and Michigan canal during the four years period above referred to was 8.6 tons of total organic nitrogen per 24 hours throughout the year, or the average for the four years. During the year 1899 the average was slightly greater than this, namely, 9 tons per 24 hours.

Now of the total organic nitrogen represented in the table above, it is to be noted that two tons per 24 hours are derived from the lake water, which is drawn in through the Illi-
9003 nois river, and consequently does not originally constitute part of the organic matter of the sewage discharged directly into the Chicago river.

9004 Table No. 2 is as follows:

No. 2. A. W. P.

Average, Illinois and Michigan Canal, 1896-9—8.6.

Average, Illinois and Michigan Canal, 1899—9.

Of the total organic nitrogen above, 2. tons per 24 hours were contained in the diluting Lake water drawn through the Chicago River.

9005 Table No. 3 of this series represents the total nitrogen,—that is the nitrogen in the form of free or saline ammonia, and the total organic nitrogen, since nitrogen in other forms is not present in any considerable quantity ordinarily in these waters, and consequently such other forms have been excluded from this table for reasons which I have already stated in my testimony concerning these particular tables.

Column No. 1 in this table gives the list of months, column No. 2 representing free ammonia. The figures in the columns represent the sum of the free ammonias which appear in table No. 1 under the year 1900.

Column No. 3 contains the figures which appear in column No. 4 of table No. 2, which represents the sum of the total organic nitrogen discharged by the two canals per 24 hours during the year 1900.

Column No. 4 of table No. 3 contains the sum of the quantities of the free ammonias represented in column No. 2 of this table, and the quantities of total organic nitrogen recorded in column No. 3 of this table.

Column No. 5 of table No. 3 contains the figures brought over from the last column in table No. 1, which represent the discharge in tons per 24 hours of nitrogen as free am-
9006 monia conveyed by the two canals into the Desplaines river and thence into the Illinois.

Column No. 6 contains the figures representing the mean daily discharge in tons of total organic nitrogen conveyed by the two canals into the Desplaines river and thence into the Illinois, and is brought over from the last column in table 2.

Column No. 7 of table No. 3, has the figures which represent the sum of the two next preceding columns, which figures give in tons per 24 hours the quantities of total nitrogen, that is nitrogen as free ammonia, and total organic nitrogen determined by the Kjel Dahl process, discharged by the two canals; consequently all that discharged in Chicago sewage through these two canals into the Desplaines and thence into the Illinois.

The average discharge of nitrogen in the form of free ammonia, plus that in the form of the total organic nitrogen by the Illinois and Michigan canal for the four years, 1896 to 1899 inclusive, was 30.5 tons per 24 hours. The average for the year 1899 being 31.6 tons per 24 hours. Of this total nitrogen 2.2 tons per 24 hours came in the diluting water drawn through the Chicago river directly from the lake. Subtracting this from the totals above given, we find that the average
9007 quantity of nitrogen in the form of free or saline ammonia and that designated as total organic nitrogen discharged in Chicago sewage by the two canals, that is the main drainage channel and the Illinois and Michigan canal, into the Desplaines and thence into the Illinois river, was 40 tons per 24 hours, the mean for the two years, 1900 and 1901 or 31.1 per cent more than the average for the four preceding years, and 26.5 per cent more than was discharged by the Illinois and Michigan canal in the year 1899. The increase in the quantities of nitrogen discharged into the Desplaines river through the two canals at Lockport and Joliet is in part doubt-

less due to the increase in population and industries contributing to Chicago's sewage, and in part it is due to the fact that a considerable proportion of the contents of the Chicago river was formerly, from time to time discharged into the lake, but is now through the operation of the drainage channel, sent into the Desplaines and thence into the Illinois.

Table No. 3 is as follows:

9008

No. 3 A. W. P.

TABLE XXIV.

QUANTITIES OF NITROGEN DISCHARGED INTO THE ILLINOIS RIVER IN CHICAGO SEWAGE.

Average, Illinois and Michigan Canal 1896-9—30.5.

Average, Illinois and Michigan Canal, 1899—31.6.

Of the total Nitrogen above, 2.2 tons were contained in the diluting Lake water drawn through the Chicago river.

$\frac{(41.09+43.31)-4.4}{2} = 40.$ tons, the average quantity discharged into the Desplaines and thence into the Illinois river, or 31.1 per cent more than the average for the four preceding years and 26.5 per cent more than in 1899.

9009 Q. Professor, have you any data which show the quantities of organic matters in the Illinois river near its mouth prior to the opening of the Chicago drainage canal and since that time?

A. I have.

Q. Will you please present that data at this time and state in what shape you have prepared the data?

A. I have the data in tables similar to those which we have just been discussing, and which refer to the Illinois and Michigan canal and the Chicago main drainage channel, or sanitary canal, and in addition I have some plates upon which there are lines drawn which show graphically the relative proportions at the different seasons of the year, and at different points along the streams in question.

JUDGE SPRINGER: These will be numbered as the explanation is proceeded with and will be inserted into the record at the time of the explanation. I offer these tables in evidence, to be incorporated in the testimony at the places at which the explanations will be made. The tables will be numbered 4, 5, 6, 7, 8 and 9.

MR. JEFFRIES: I object to the introduction or reading in evidence of tables 4, 5, 6, 7, and move to strike out table 2, which has just previously been read in evidence, for the 9010 reason that it does not correctly disclose the amount or extent of the sewage discharges by comparison or otherwise, from the city of Chicago into the drainage canal and thence into the Illinois river, nor does it disclose by comparison or otherwise the extent and amount of pollution and infection in the Illinois river at Kampsville, in that the chemical constituents used in the table do not reveal all of the chemical constituents and substances contained in the sewage of Chicago and in the polluted and infected matter contained in the Illinois river at Kampsville.

Table 2 undertakes to disclose the total tonnage per 24 hours, of organic nitrogen which passed through the Illinois and Michigan canal and the sanitary canal in 1900 and 1901, when in fact the sewage and total solids of the sewage at that time was not in that state which would enable any correct or reliable determinations therefrom.

And I move to strike out tables 4, 5, 6, and 7 for the additional reason that they refer to the tonnage of organic nitrogen,

nitrates and nitrites, and nitrogen as albuminoid ammonia when, as above stated, these constituents are not correctly represented and from them no reliable conclusions can be drawn as to the amount and extent of the polluted and infected material in the water of the Illinois river at Kampsville
9011 during the period covered by the tables, and for the further reason that the tables which have been read in evidence by this witness disclose that there are yet large quantities of free ammonia and other chemical constituents that have not been reduced to nitrates or nitrites, and are not contained in these tables, so that no comparison and no conclusions as to the extent and volume of polluted and infected material at Kampsville is disclosed by the table in question.

And I object to the tables being read or introduced in evidence for the further reason that as tables of averages they fail to disclose conditions, of more than ordinary consequence, which are correct determinations of the issues in this case, and for the further reason that they fail to disclose both the minimum and the maximum conditions with reference to the subject matter treated.

JUDGE SPRINGER: Counsel for defendants suggest that these objections are argumentative and go merely to the weight of the evidence and not to its admissibility or competency. As an argument, counsel assumes to draw conclusions which only a sanitary expert can submit, and counsel has not qualified as such. The objection as to the failure of these tables to disclose minimum and maximum constituents—those have already appeared in the previous tables as will be explained hereafter.

9012 MR. JEFFRIES: In addition to what has been stated in my objection and in reply to Judge Springer's statement, I suggest to the Court that the objection is not argumentative but may be based as well upon the statement of witness now on the stand and the admission of counsel for the defense, to the effect that the nitrogen ascertainments and the ascertainments of the nitrogenous matter in water is so unreliable in regard to the ascertainment of the mixture of the waters, that it could not be used in that connection, and if unreliable for that purpose, it must also be unreliable for the purpose of determining the extent or amount of polluted or infected material in the water at any given point.

JUDGE SPRINGER: Counsel's objections are still argumentative and comment upon testimony heretofore submitted, giving his conclusion as to the effect of such testimony; but I submit that the testimony is in the record and speaks for itself and it will be considered at the proper time.

Q. Professor, did you prepare any graphic plates in connection with these data?

A. I did.

Q. And in explanation thereof?

A. I have done so.

Q. As you proceed with your explanation of these tables, you may present those graphic plates and at the time of 9013 their presentation I will offer them in evidence, that they may be incorporated in the evidence at the place where the explanation occurs.

MR. JEFFRIES: I object to the witness introducing any evidence of graphic plates, or testifying therefrom, which graphic plates are based upon the tables just offered in evidence, for the same reasons stated in my objection to the introduction and reading in evidence of the tables themselves.

JUDGE SPRINGER: You may now proceed, professor, with the explanation of the tables and also the graphic plates, when you reach them, and make such explanation of them as you desire to submit.

A. These tables numbered 4, 5, 6, 7, 8, and 9 of this series give the mean daily discharge of nitrogen in the form of free or saline ammonia, in the form of albuminoid ammonia, the total organic nitrogen and nitrogen as nitrites, and the nitrogen as nitrates, in the waters of the Illinois river discharged over the Kampsville dam for the years 1897 to 1902 inclusive, and also show the average discharge per 24 hours for the first six months and the second six months in each year referred to, and the average discharge for the entire year. Also the average discharge for the period of three years prior to 1900, 9014 and the average daily discharge for the three year period 1900, 1901 and 1902, inclusive, thus covering the three year period immediately preceding the opening of the

Chicago main drainage channel and the three year period immediately subsequent thereto.

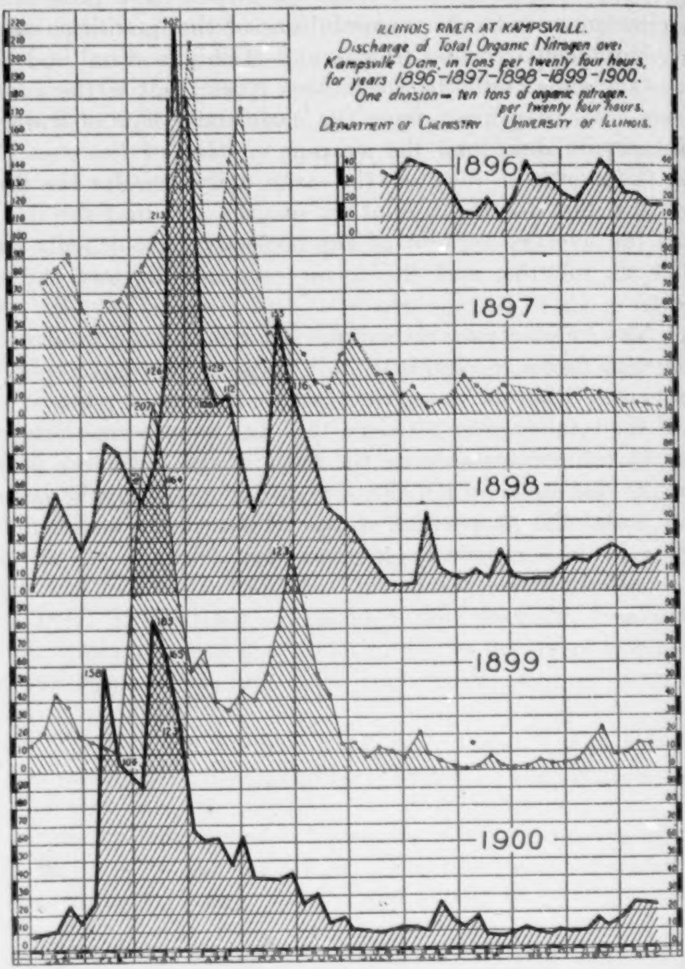
The computations of these quantities have been made in similar manner to the computations of the quantities of nitrogen discharged by the Illinois and Michigan canal and by the sanitary canal into the Desplaines river; that is the computations have been made from the mean daily flow of water over Kampsville dam, and the average content of the constituents for the month in question, the mean daily flow for the first six months, that for the second six months and that for the year, and the average content of the respective constituents for the first six months, and the second six months and the entire year.

The calculations respecting the quantities of nitrogen in different forms of combination in these waters have been made in several different ways, those which appear in plate 41 represent the total organic nitrogen that has been in tons discharged per 24 hours calculated on the basis of the discharge of water for the day upon which the sample for analyses was collected, and the proportion of the total organic nitrogen found
9015 in the sample collected that day.

Plate 41 is as follows:

9016

No. 41.—A. W. P.



9017 The lines of this plate show how considerable were the seasonal variations in the weights of organic nitrogen discharged over the dam at this point during the years 1896 to 1900 inclusive, only the last five months in 1896 being considered because our examinations of the water of the Illinois river at Kampsville began in the latter part of July of that year.

Comparison of these curves with each other shows that during the year 1900, that is, the first year after the opening of the Chicago main drainage channel, the weights of organic nitrogen carried by the water of the Illinois river over the dam at Kampsville, just as they are about to discharge into the Mississippi at Grafton, thirty miles below, were generally less than they were during the preceding years, during both the high water period and the low water period, except that in 1899, during the period ranging from the middle of August to the middle of November, when the flow in the river was extremely low, the quantities of organic nitrogen carried were less than in 1900.

Calculations based upon monthly averages both for the data of the analyses and for the flow of the river show similar but of course less irregular variations throughout the years.

Table No. 4 of this series is as follows:

A. W. P. NO. 4.

9018 TOTAL ORGANIC NITROGEN.

QUANTITIES OF NITROGEN IN THE WATERS OF THE ILLINOIS RIVER AT KAMPSVILLE. TONS DISCHARGED PER 24 HOURS. From monthly averages, average for 1st 6 months; average for 2nd 6 months and yearly averages of flows and constituents. Tons of T. O. N. per 24 hours.

est.

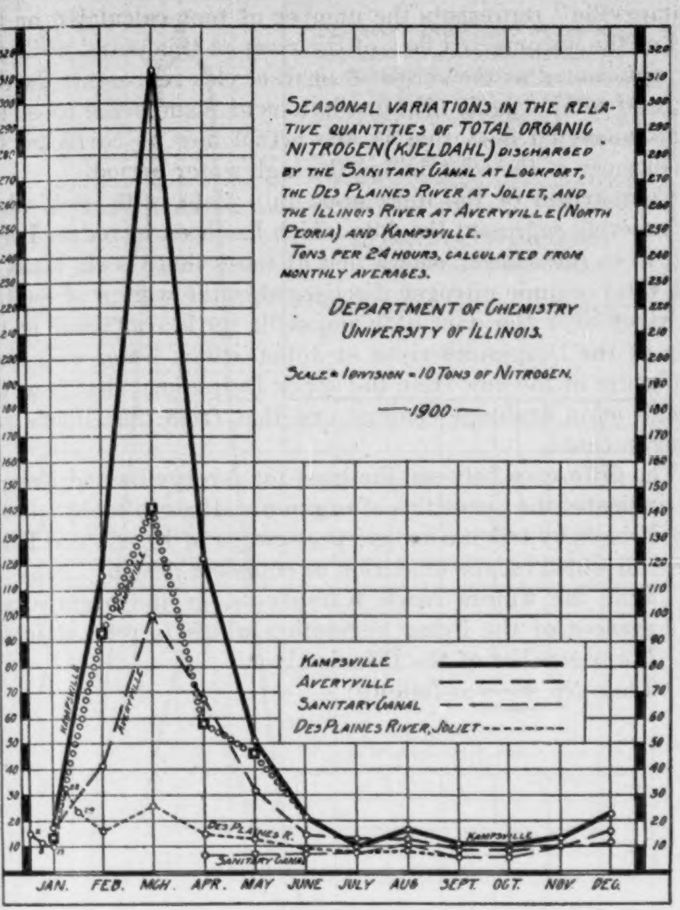
For 1902 calc. from Alb. N. on basis of latter—40% of T. O. N.

9019 Table No. 4 records the discharges of total organic nitrogen in tons in the waters of the Illinois river for each 24 hours of each month during the years 1897 to 1901 inclusive, and for 1902 the data for the last three months in 1901, and for the entire year 1902, having been computed from the tons of nitrogen as albuminoid ammonia discharged on the basis of the latter constituting 40 per cent of the total organic nitrogen.

The figures of this table representing the mean daily discharge of total organic nitrogen for the year 1900 have been represented upon plate No. 42, of this series, together with similar lines referring to the quantities carried by the waters of these streams at certain other points during the same period.

Plate No. 42 is as follows:

No. 42.—A. W. P.



SEASONAL VARIATIONS IN THE RELATIVE QUANTITIES OF TOTAL ORGANIC NITROGEN (KJELDAHL) DISCHARGED BY THE SANITARY CANAL AT LOCKPORT, THE DES PLAINES RIVER AT JOLIET, AND THE ILLINOIS RIVER AT AVERYVILLE (NORTH PEORIA) AND KAMPSVILLE.

9021 Upon Plate No. 42 there are two lines for Kampsville, for a portion of the year, the heavy continuous line labeled "Kampsville" represents the number of tons calculated on the basis of the uncorrected flow of the river at this point, while the line represented as the series of small circles represents the discharge of total organic nitrogen in tons at Kampsville based upon the corrected flow, that is, the actual flow as corrected for submergence of the wier during the high water period.

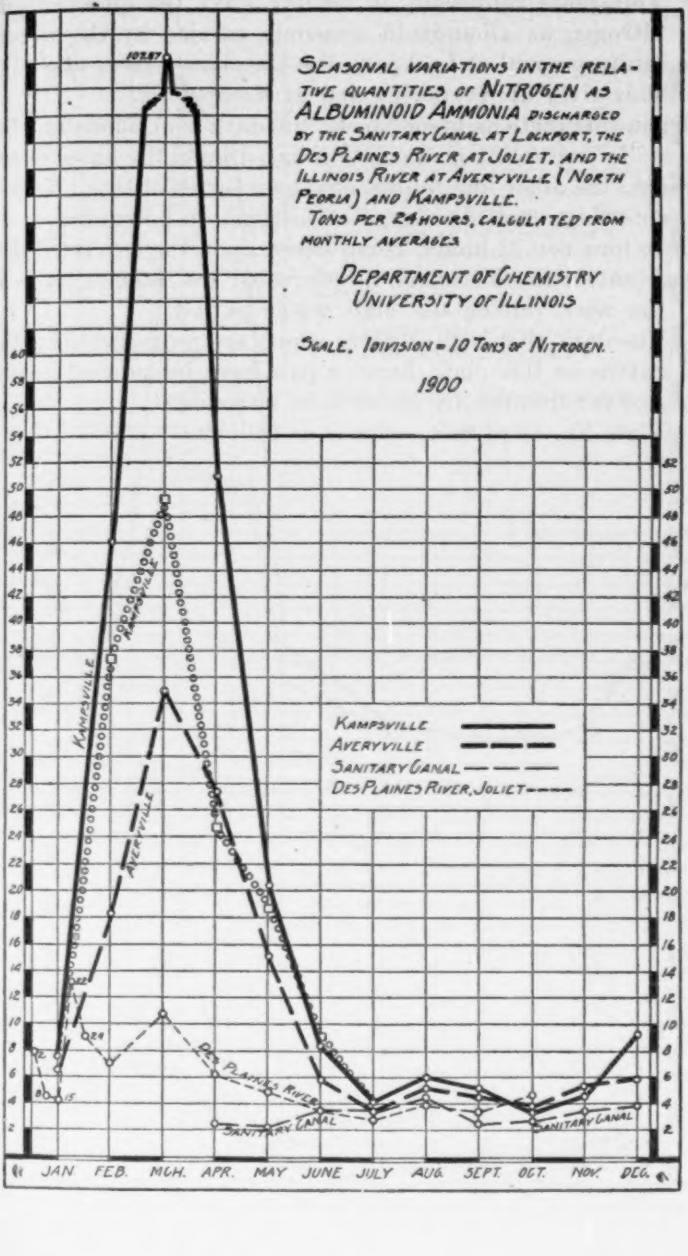
Comparison of the lines upon this plate, with each other, which merely represent the data which has been introduced or is about to be introduced, shows that at times there is six times as much total organic nitrogen discharged in the waters of the Illinois river over the dam at Kampsville as is contained in the water of the Desplaines river at Joliet, which latter comprizes the mixture of the flow from the upper Desplaines, that from the Chicago main drainage channel and that from the Illinois and Michigan canal.

The difference between the lines for Averyville and Kampsville, indicates the quantities of organic matters brought into the lower Illinois by tributaries and the sewage of Peoria and Pekin and so on which escape oxidation or complete destruction by the time the waters reach Kampsville, or the organic sub-
9022 stances of the living vegetation which is present in the lower reaches of the Illinois river.

Plate No. 43 is as follows:

9023

No. 43.—A. W. P.



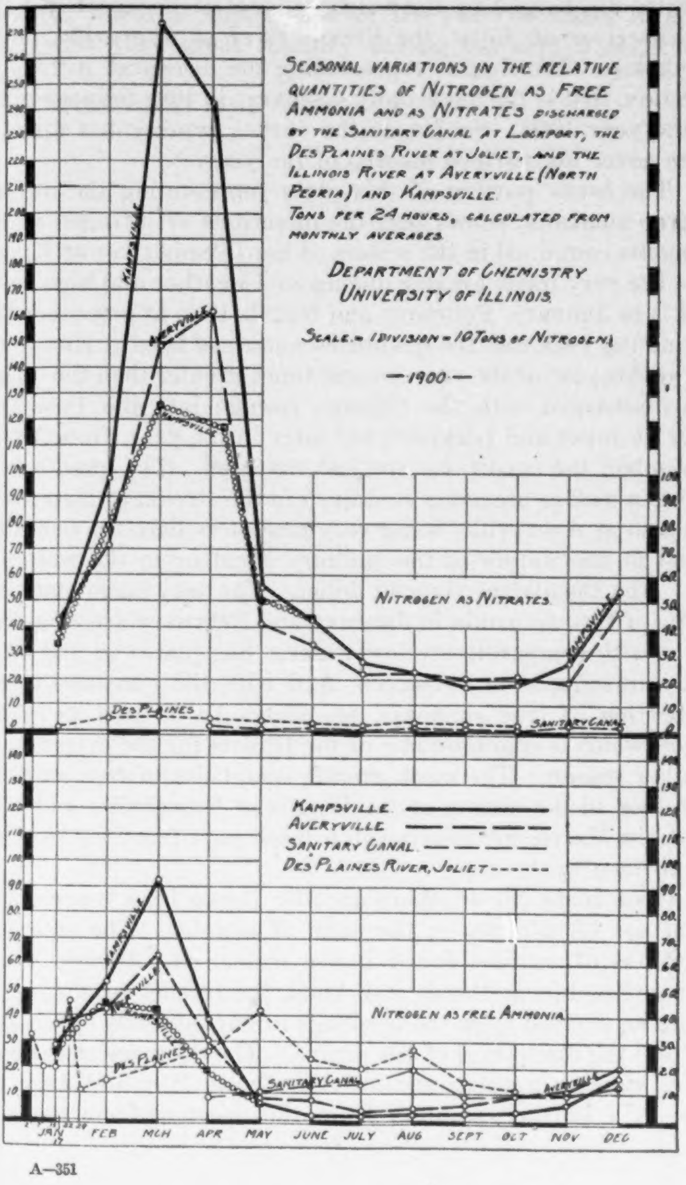
9024 This plate represents in similar ways the quantities of nitrogen as albuminoid ammonia carried by the waters of the sanitary canal at Lockport, the Desplaines river at Joliet, the Illinois river at Averyville and at Kampsville.

Upon this plate as upon No. 42, the dark continuous line for Kampsville represents a calculation based upon the uncorrected discharge; the other line represented as a series of small circles, represents the actual discharge of nitrogen as albuminoid ammonia in tons per 24 hours, being based upon the corrected discharge, that is the discharge as corrected for submergence of the wier, during the high water period.

9025 The data, that is the figures which are represented by the curves on this plate, have in part been introduced in evidence, and for the rest are about to be introduced.

Plate No. 44 of this series is as follows:

No. 44.—A. W. P.



SEASONAL VARIATIONS IN THE RELATIVE QUANTITIES OF NITROGEN AS FREE AMMONIA AND AS NITRATES DISCHARGED BY THE SANITARY CANAL AT LOCKPORT, THE DES PLAINES RIVER AT JOLIET, AND THE ILLINOIS RIVER AT AVERYVILLE (NORTH PEORIA) AND KAMPSVILLE.
TONS PER 24 HOURS, CALCULATED FROM MONTHLY AVERAGES.

9027 It represents by means of curves, seasonal variations in the relative quantities of nitrogen as free ammonia and as nitrates discharged by the sanitary canal at Lockport, the Desplaines river at Joliet, the Illinois river at Averyville, and at Kankakee. The figures representing the discharge in tons per 24 hours, that is the mean daily discharge in tons for each month in the year 1900. So far as the curves represented upon the plate cover the various months of the year.

The lower portion of this plate representing the nitrogen as free ammonia, shows that the quantities of nitrogen as free ammonia contained in the waters of the Illinois river at Kampsville are very much greater during cold weather and high water, that is in January, February and March, than at any other time during the year, and the quantities contained here at Kampsville are at this part of the year several times greater than the quantities discharged with the Chicago sewage into the Desplaines river at Joliet and Lockport, but later in the year, from May to November, the conditions are just reversed. The quantities of nitrogen as free ammonia contained in the stream at Kampsville and also at Averyville, being very much less than the quantities found in the waters of the sanitary canal or in the waters of the Desplaines river at Joliet. The very large quantities
9028 of free ammonia in January and February are coincident with comparatively low water. See plates 18 and 19 already introduced in evidence. And with the excessively high proportion of free ammonia, see plates 10, 14 and 39 of this series, which is characteristic of the Illinois for the extreme cold weather season. The much greater quantities of free ammonia contained in the waters of the Illinois at Kampsville and other points in March, are derived in a large part from the rain and the surface wash.

Upon plate No. 44, there are also shown lines representing quantities of nitrogen in the form of nitrates. The enormous quantities of nitrates found in the water at Averyville and Kampsville during March and April, the freshet season, are in the main, derived from the leechings or surface soils by the run-offs and the discharges of tile drains. The decrease at the coming of warmer weather and lower water in May and June, results in a partial cessation from this leeching,from the partial oxidation of the supply of nitrates in the soil and from the assimilation of nitrates by the vegetation, especially that of the plankton, which at this season of the year increases in abundance with very great rapidity during the cold weather season.

Plate No. 45 is as follows:

9030 It represents by means of curves the flow of water over the Kampsville dam. stated in cubic feet per second. The proportions of chlorine,—and for the years 1896 to 1900 inclusive, also the proportions of chlorine contained in the various samples of water collected during these years, and the data of which are given in tables 1 to 80 inclusive heretofore offered in evidence, and the results of computations of the weights of chlorine carried by the water of the Illinois river at Kampsville as it is discharged over the Kampsville dam, the quantity stated in tons every 24 hours during the day the collection was made and for the mean flow of that day.

Table No. 5 of this series is as follows:

9031 QUANTITIES OF NITROGEN IN THE WATER OF THE ILLINOIS RIVER. TONS DISCHARGED PER 24 HOURS; Calculated from monthly averages of flow and constituents.

Decrease 30 per cent.

9032 It gives the discharge of nitrogen as albuminoid ammonia in the waters of the Illinois river passing over the Kampsville dam in tons per 24 hours, for each month of the years 1897 to 1903, inclusive, and gives also the average daily discharge during the first six months and during the second six months, and for the period, the three year period; also the average, that is, the period prior to the opening of the Chicago main drainage channel and the average for the three years subsequent to that opening, these averages being 20.08 tons per 24 hours, and 14.07 tons per 24 hours, respectively, showing a decrease in the weight or quantity of nitrogen as albuminoid ammonia discharged by the waters of the Illionis river at Kampsville in the second period of three years, that is, the period following the opening of the Chicago main drainage channel as compared with the three years prior thereto, which decrease amounts to 30 per cent. in weight.

The quantities representing the daily discharge of nitrogen as albuminoid ammonia for each month of the year 1900 appearing in this table, have been represented upon plate No. 43, which has just been in part discussed.

These figures and the quantities represented by them being calculated from the flow corrected for submergence of the wier, at Kampsville, and from the monthly averages of constituents, all of which have heretofore been introduced as evidence
9033 in my testimony.

Table No. 6 of this series is as follows:

Year	9.04	13.1	10.2	14.2	9.6	9.6
3 years	10.78			11.1		

9035 It gives similar data respecting the discharge of nitrogen as free ammonia or saline ammonia in the waters of the Illinois river passing over the Kampsville dam during the years 1897 to 1902, inclusive. It gives also the mean daily discharge for the first six months, second six months, and for the year, and the mean discharge for the entire three year period prior to the opening of the main drainage channel, and for the three year period immediately subsequent thereto, which averages are as follows:

For the three years prior to the opening of the Chicago main drainage channel 10.78 tons of nitrogen as free ammonia every 24 hours, and for the three year period, 1900 to 1902, subsequent to the opening of the Chicago main drainage channel, 11.1 tons of nitrogen as free ammonia every 24 hours, thus showing an increase in the quantity of nitrogen as free ammonia discharged by the waters of the Illinois river at this point in the second period over the quantity discharged during the first period, amounting to practically three per cent., the figure on this plate being 2.968 tons per 24 hours.

Table No. 7 of this series is as follows:

9036

QUANTITIES OF NITROGEN IN THE WATERS OF THE ILLINOIS RIVER AT KAMPSVILLE. TONS DISCHARGED PER 24 HOURS. FROM AVERAGE FOR 1st 6 MO., AVERAGE FOR 2nd 6 MO., AND YEARLY AVERAGE OF FLOWS AND CONSTITUENTS. NITRITES.

Year	2.9	2.59	1.2	1.1	.767	1.98			

2.23 1.282

Decrease 42.5 per cent.

Shift of high water period in 1902 to summer and fall.

9037 It represents the quantities of nitrogen as nitrites discharged into the waters of the Illinois river over the Kampsville dam for the period 1897 to 1902, inclusive. The discharges appearing as the average daily amont carried by these waters for each month of the year indicated respectively, the average daily amount in tons during the first six months, the average daily amount during the second six months and the average daily amount during the whole year, and also the averages for the three year period prior to the opening of the Chicago main drainage channel and the average for the three years subsequent thereto, the figures for these two periods being as follows:

For the first 2.23 tons per 24 hours,
For the second, 1.282 tons per 24 hours,

showing that subsequent to the opening of the Chicago main drainage channel the proportions of nitrogen as nitrites discharged by the waters of the Illinois river at Kampsville were 42½ per cent. less than they were during the three year period immediately prior thereto.

Inspection of the figures representing the data for the year 1902 in this plate, shows the shifting during this year of the high
nitrites period, consequent upon the shifting of the high
9038 water period as shown upon plates 19 and 18 heretofore
introduced in evidence, which plates show the discharges of water by the Illinois river at Kampsville for the years 1896 to 1902, inclusive, and show the fact that is given in detail in the tables of discharge which have been heretofore introduced in evidence, that while usually the high water period in the lower Illinois river comes in March and April, in the year 1902 the highest water of the year came in July and August, and for the last nine months of the year the water was throughout, unusually high, in fact, the discharge for the year 1902, was considerably higher than during any other year of this period, that is, of the years 1896 to 1902, inclusive.

Table No. 8 of this series is as follows:

9039 8. A. W. P.

QUANTITIES OF NITROGEN AS NITRATES IN THE WATERS OF THE ILLINOIS RIVER AT KAMPSVILLE. TONS DISCHARGED PER 24 HOURS. FROM 1st 6 MO.; 2nd 6 MO.; MONTHLY AND YEARLY AVERAGES OF CONSTITUENTS AND FLOWS.

Year	68.	32.71	25.12	50.51	31.33	60.24

9040 It represents the discharge in tons per 24 hours of nitrogen as nitrates, contained in the waters of the Illinois river passing over the dam at Kampsville during the years 1897 to 1902, inclusive, and includes also the average daily discharge for the first six months, and the second six months, and the year.

The data of this table touching the year 1900, has been used in making the curve for this point shown upon plate No. 44 heretofore introduced in evidence .

Adjourned until 10:00 a. m., following day, Friday, November 20th, 1903.

9041 10:00 a. m., Friday, November 20, 1903. Continuation pursuant to adjournment.

Present, the Commissioner and same counsel representing the respective parties.

PROF. ARTHUR W. PALMER,

resumed the stand for further direct-examination, by Judge Springer, and testified as follows:

Q. Professor, at the time of adjournment yesterday we were considering table No. 8 of this series, and you had just referred to the data of this table touching the year 1900, and with reference to the curves shown upon plate 44 heretofore introduced in evidence. Will you proceed with the explanation of that table and the plate referred to?

A. Comparison of the data for the various years shows that during the year 1897 the quantities of nitrates discharged into the waters of the Illionis river at Kampsville, were very much greater throughout the year, that is, throughout the high water season, and also in general throughout the low water season, than they were in the years 1898 and 1899.

The proportions discharged during the years 1898 and 9042 1899, were on the average considerably less than during the years 1900 and 1901 and still more considerably less than during the year 1902, though in no one of the years subsequent to the opening of the Chicago main drainage channel were the quantities of nitrates in the water of the Illinois at Kampsville so great as they were during the year 1898.

It is notable that for the year 1902 the quantities of nitrates carried in the waters of the Illinois river at Kampsville were much greater during the latter part of the year than during the first two months, and that during what is ordinarily the low water season in the Illinois, that is, the last six months in the year, the nitrates at this point were present in very considerably greater quantities than during the similar periods of the five preceding years, which fact is in the main due to the high water which existed during this portion of the year 1902, an unusual condition as referred to in my testimony above.

The comparison of the monthly averages of the discharges of nitrogen as nitrates per 24 hours for the two points, Kampsville and Averyvile, shown in the upper part of plate No. 44

heretofore introduced in evidence, shows that during the high water season the discharge of nitrates at Kampsville was less than the discharge at Averyville, while in the latter part
9043 of the year, especially during the months of July, August, September and October, the quantities are approximately equal at the two points, in the latter part, that is, in the months of November and December, there being a somewhat greater quantity of nitrates discharged by the waters of the Illinois at Kampsville and at Averyvile.

Table No. 9 of this series is as follows:

9044

NO. 9.

QUANTITIES OF NITROGEN IN THE WATERS OF THE ILLINOIS RIVER AT KAMPSVILLE. TONS DISCHARGED PER 24 HOURS. FROM YEARLY AVERAGES OF FLOWS AND CONSTITUENTS.

Year	Nitrogen as nitrites.	Nitrogen as nitrates..	Nitrogen as free ammonia ..	Total organic..	Total nitrogen	Albuminoid	Oxygen consumed
1897	3.86	65.83	15.4	47.8	132.89	21.94	478.4
1898	2.97	32.71	16.01	43.91	95.6	20.79	503.7
1899	1.33	25.12	10.05	28.94	65.44	12.12	317.9
Aver.	2.7	41.22	13.82	40.22	97.93	18.28	433.3
1900	1.33	50.51	13.22	31.87	96.93	12.62	327.2
1901	1.12	31.33	9.62	23.	65.07	8.67	241.2
1902	1.996	60.24	20.95	43.1	126.18	17.24	504.
Aver.	1.479	47.36	14.6	32.65	96.06	12.84	357.5

9045 This table shows the discharge of nitrogen as nitrites, nitrates, free ammonia, the total organic and the total nitrogen; also the albuminoid nitrogen and the oxygen consumed by the waters of the Illinois river discharged over the Kampsville dam in tons per 24 hours, during the years 1897 to 1900, inclusive. The figures representing the average daily discharge of the varoius constituents mentioned during each of the years referred to and being calculated from the mean yearly flow and the yearly average of the given constituent.

The total nitrogen referred to, the figures representing the quantities of which appear in column 6, consists of the sum of the nitrogen as nitrites, the nitrogen as nitrates, the nitrogen as free ammonia and the total organic nitrogen, and consequently represent all of the nitrogen contained in the waters in combination with different substances. I explained that to distinguish from nitrogen gas, which may be dissolved in the water and which may be formed by the decomposition of any of these substances, or be dissolved from the air.

In addition to the yearly averages, there are given averages for each of the three year periods.

Table No. 10 of this series is as follows:

9046 NO. 10, A. W. P.

QUANTITIES OF NITROGEN IN THE WATERS OF THE ILLINOIS RIVER AT KAMPSVILLE. TONS DISCHARGED PER 24 HOURS. FROM 1st 6 MO. AVERAGES OF FLOWS AND CONSTITUENTS.

KAMPSVILLE.

Year	Nitrogen as nitrites..	Nitrogen as nitrates..	Nitrogen as free ammonia ..	Total organic..	Total nitrogen	Albuminoid	Oxygen consumed

9053 Table 13 shows the quantities of nitrogen in the waters of the Illinois river at Kampsville in tons discharged per 24 hours, calculated from yearly averages of flows, and yearly averages of the various constituents, the nitrogen as nitrites and as nitrates, as free ammonia, the total organic as determined by the Kjel Dahl process, the total nitrogen, that is, the sum of that as nitrates, that as nitrites, that as free ammonia and the organic nitrogen, and in addition to these gives similar data regarding the nitrogen as albuminoid ammonia and also the quantities of oxygen consumed by the waters. The averages for the three years preceding the opening of the Chicago main drainage channel and the averages for the three years immediately subsequent thereto, together with general averages for each of these two three year periods.

The organic nitrogen ordinarily as determined by the Kjel Dahl process is for the year 1902, in this table computed from the nitrogen as albuminoid ammonia on the basis of the latter constituting 40 per cent. of the total organic, the Kjel Dahl determination of organic nitrogen. At the bottom of the table there are also given the mean yearly flows or dicharges of water over the Kampsville dam corrected for submergence of the wier, for the years 1897 to 1902, inclusive.

9054 Q. Have you data showing the flows at that time?

A. I have.

Q. Will you please put that in the record?

A. They are as follows?

For the year 1896, the mean daily flow in

January, was	20,538 cubic feet per second,
February,	18,081
March,	18,158
April,	11,711
May,	11,729
June,	14,193

The average for the six months, or the mean daily flow for the six months, is 15,752 cubic feet per second.

In July the flow was 9,337 cubic feet per second,

August,	15,490
September,	7,060
October,	8,292
November,	7,935
December,	7,353

The average for the six months being 9,245, and the mean flow for the year being 12,498 cubic feet per second.

9055 For the year 1897:

January,	21,225 cubic feet per second.
February,	21,109
March,	31,820
April,	51,139
May,	29,117
June,	8,406

The average for the six months being 27,136.

July,	10,394 cubic feet per second.
August,	3,603
September,	5,404
October,	5,188
November,	5,760
December,	1,935

The average for the second six months being 5,381 and the average for the year, 16,256 cubic feet per second.

9056 For the year 1898:

January,	8,157 cubic feet per second.
February,	15,574
March,	25,987
April,	45,980
May,	24,062
June,	23,935

The average for the six months being 23,949.

July	8,919 cubic feet per second.
August,	6,034
September,	6,188
October,	5,098
November,	11,824
December,	9,607

The average for the second six months being 7,945, and the average for the year being 15,947 cubic feet per second.

9057 For the year 1899:

January,	11,546 cubic feet per second.
February,	8,253
March,	23,901
April,	18,570
May,	16,531
June,	16,026

The average for the six months being 15,804 cubic feet per second.

July,	4,602 cubic feet per second.
August,	3,958
September,	1,272
October,	1,459
November,	3,645
December,	4,197

The mean for the six months being 3,189, and the average for the year being 9,497 cubic feet per second.

9058 For the year 1900:

January,	6,497 cubic feet per second,
February,	15,793
March,	35,199
April,	28,133
May,	15,722
June,	10,835

The average for the six months being 18,697 cubic feet per second.

July,	7,270 feet per second,
August,	7,574
September,	6,422
October,	4,773
November,	6,386
December,	11,785

The mean for the second six months being 7,369 and the mean for the year being 13,033 cubic feet per second.

9059 For the year 1901:

January,	11,526 cubic feet per second,
February,	10,400
March,	18,542
April,	30,537
May,	12,803
June,	6,666

The mean for the six months being 15,087 cubic feet per second.

July,	5,210 cubic feet per second,
August,	3,748
September,	3,450
October,	3,137
November,	3,766
December,	4,257

The average for the six months being 3,925 and the average for the year being 9,506 cubic feet per second.

9060 For the year 1902:

January,	5,032 cubic feet per second,
February,	3,667
March,	13,779
April,	16,375
May,	12,296
June,	15,495

The average for the six months being 11,107 cubic feet per second.

July,	43,537 cubic feet per second,
August,	36,670
September,	16,830
October,	17,809
November,	19,360
December,	18,743

The mean for the second six months being 25,506, and the mean for the year being 18,306 cubic feet per second. That is, the monthly and six months averages have been computed from the tables of mean daily discharges of water over the Kampsville dam, which have heretofore been introduced in evidence by me in this case.

Table No. 14 of this series is as follows:

9061

NO. 14.—A. W. P.

TABLE XX.

QUANTITIES OF NITROGEN IN THE WATERS OF THE ILLINOIS RIVER AT KAMPSVILLE. TONS DISCHARGED PER 24 HOURS; CALCULATED FROM THE AVERAGE FLOW FOR EACH PERIOD OF THREE YEARS AND THE AVERAGE PROPORTION OF THE CONSTITUENT FOR SAME PERIOD.

1st period, 1897-8-9, average flow—13,900 cubic feet per second or 37,530,000 tons of water per 24 hours.

2nd period, 1900-1-2, average flow—13,614 cubic feet per second, or 36,750,000 tons of water per 24 hours.

NITROGEN AS	Parts per million.		Tons per 24 hours.		Differences.
	1st period 1897-8-9	2nd period 1900-1-2	1st period 1897-8-9	2nd period 1900-1-2	
Nitrites	.067	.005	2.52	1.49	Decrease 40.8 p. c.
Nitrates	1.103	1.276	41.4	46.9	Increase 13.3 p. c.
Free Ammonia	.3737	.3937	13.95	14.47	Increase 3.7 p. c.
Organic (Kjeldahl)	1.066	.888	40.	32.6	Decrease 18. p. c.
Total Nitrogen	2.6097	2.5982	97.87	95.46	Decrease 2.46 p. c.
Albuminoid Ammonia	.4665	.3495	17.5	12.84	Decrease 30.6 p. c.
Oxygen Consumed	11.7	10.7	438.	393.	Decrease 10.2 p. c.

9062 It represents the quantities of nitrogen discharged in the waters of the Illinois river over Kampsville dam in tons per 24 hours, and is calculated for the first three year period, that is the years 1897 to 1899, inclusive, immediately preceding the opening of the Chicago main drainage channel and for the three year period 1900 to 1902, inclusive, immediately following that opening.

During the first period the average flow was 13,900 cubic feet per second, or 37,530,000 tons of water per 24 hours.

During the second period the flow was 13,614 or 36,750,000 tons of water per 24 hours.

In the table there are given the average proportions of the different constituents and also the average daily discharge in tons of the constituents in question.

The nitrogen as nitrites amounted to 2.52 tons per 24 hours during the first period, and 1.49 tons per 24 hours during the second period, which shows a decrease in the quantities of this constituent discharged by the water of the Illinois river at Kampsville during the second period, as against the first, of 40.8 per cent.

The nitrates are shown by the table to have increased during the second period, the increase amounting to 13.3 per cent.

9063 The free ammonia discharged was found to be greater in quantity during the second period than during the first to the extent of 3.7 per cent.

The organic nitrogen as determined by the Kjel Dahl process was contained in smaller quantity during the second period than during the first, and as represented upon the table the decrease in weight was 18 per cent.

At the bottom of the table similar data show that the quantities of nitrogen as albuminoid ammonia decreased, the decrease as stated being 30.6 per cent.

The oxygen consumed during the first period amounted to 438 tons per 24 hours, and during the second period 393 tons per 24 hours, showing thus a decrease of 10.2 per cent subsequent to the opening of the Chicago main drainage channel.

The evidence shows conclusively that since the opening of the Chicago main drainage channel there has taken place not only a considerable diminution in the proportions of the organic matters contained in the waters of the lower Illinois river, and as they are about to discharge from that stream into the Mississippi, but that a substantial decrease of the actual quantities of the organic matters contained in these waters has oc-
9064 curred, and this notwithstanding the fact which I have testified to, already, that the quantities of organic matters conveyed in Chicago sewage into the Desplaines and thence into the upper Illinois are considerably greater now than they were before the opening of the Chicago main drainage channel.

As it has been shown in my testimony that the organic matters contained in the Chicago sewage discharged into the upper Illinois are practically destroyed or converted into vegetable matters by the time the waters reach Peoria, that is Averyville, where another great influx of sewage and other organic wastes occurs, it will be of importance to compare the condition of the water at Averyville, just above Peoria with its condition at Kampsville, 140 miles below, with respect to the quantities of organic matters carried by the stream at these two points.

The data involved in this comparison have been brought together upon table 15 of this series, which is as follows:

9065

TABLE NO. 15.—A. W. P.

TABLE XXI.

QUANTITIES OF NITROGEN IN THE WATERS OF THE ILLINOIS RIVER AT AVERYVILLE (ABOVE PEORIA.) TONS DISCHARGED PER 24 HOURS; CALCULATED FROM THE MEAN FLOW FOR EACH YEAR AND THE YEARLY AVERAGES OF CONSTITUENTS (SEE TABLE XII PAGE 81).

Year.	Mean Flow of Water.		Nitrogen as						
	Cubic ft. per second	Mil. tons per 24 hrs.	Nitrites.	Nitrates	Free Am'ia.	Org'le Kjeld'l	Total Ni'gen	Albu. Am'ia.	Oxy'n Cons'd

*Increase. - Decrease.

9066 Table 15 represents the quantities of nitrogen in the waters of the Illinois river at Averyville, above Peoria, tons discharged per 24 hours; that is, the average for the years 1897 to 1901 inclusive, and with the general averages first for the three year period before the opening of the Chicago main drainage channel and second, for the two year period immediately following, and also there are introduced here once more, for purposes of comparison, similar data with respect to Kampsville.

Comparing the averages for the three year period before the opening of the Chicago main drainage channel with the averages for the two year period subsequent thereto, and I may say here that no analyses of the waters of the Illinois river at Kampsville were made by me for the year 1902, the work at that point was discontinued—comparison of the. general averages for these two periods shows that subsequent to the year 1899 there was a decrease in the weight of nitrogen as nitrites discharged by the waters of the Illinois river at Averyville, from 5.24 tons per 24 hours to 2.34 tons per 24 hours, a decrease of 55 per cent.

The nitrates on the other hand were increased, the increase amounting to 16.85 per cent.

The nitrogen as free ammonia showed a very considerable decrease, amounting to 22.9 per cent, the total organic
9067 nitrogen, Khel Dahl, show a decrease amounting to 17.86 per cent.

The total nitrogen, that is, the sum of those before referred to, show a decrease of 6.26 per cent.

The nitrogen as albuminoid ammonia decreased in quantity 32.78 per cent.

The oxygen consumed by the waters of the Illinois at this point showed a decrease amounting to 25.55 per cent.

Comparing the data for Averyville with those for Kampsville for the years 1897 to 1899, inclusive, the data for Kampsville having been taken from the tables heretofore introduced by me in evidence, shows that between Averyville and Kampsville there is a very considerable decrease in the quantities of nitrites carried by the waters of the Illinois river, this amounting to 48.47 per cent.

That the nitrogen as nitrates during this period increased 14.5 per cent. The nitrogen as free ammonia decreased 43.56 per cent. The total organic nitrogen as determined by the Kjel Dahl process increased 62.15 per cent, this increase being due to the organic matters brought in by the various tributaries of the

Illinois, the discharges of organic matters at Peoria and Pekin, and the wash from the immediate water-shed of the river, and including the vegetation of the river which has subsisted
9968 upon refuse organic matters, introduced at points above
and from the conversion of mineral matters contained in the water, including nitrates, nitrites free ammonia, carbon and so on, into the substances of the vegetation which is so luxuriant in the lower reaches of the Illinois, the total nitrogen is found to increase 7.47 per cent during this period between Averyville and Kampsville.

The albuminoid nitrogen increased between these two points to the extent of 44.39 per cent, considerably less in proportion than did the total organic nitrogen.

The oxygen consumed by the waters increased in quantity between these two points to the extent of 45 per cent.

Comparing the periods after the opening of the Chicago main drainage channel and for the purpose of putting this comparison upon a more reasonable basis I have calculated an average for the content, that is the quantity of these constituents contained in the waters of the Illinois at Kampsville for the two year period following the opening of the Chicago main drainage channel since we have data for Averyville only for this period, we find generally as follows:

A decrease in the quantities of nitrogen as nitrites from
9069 2.34 tons per 24 hours at Averyville, to 1.22 tons per 24
hours at Kampsville, a decrease of 47.85 per cent, which is almost as considerable in percentage as the decrease between these two points in the earlier years, while the actual quantities themselves are about one-half the quantities contained in the water at these two points during the previous period, that is the three years prior to the opening of the Chicago main drainage channel. The nitrates show a change between Averyville and Kampsville, that is, a decrease, amounting to 5.49 per cent, while in the former period between these two points there occurred an increase in the weights of nitrogen as nitrates. The nitrogen as free ammonia were for Averyville during this period 18.88 tons per 24 hours; the quantities for Kampsville being 11.24 tons per 24 hours, showing a decrease of 40.46 per cent between the two points, which is practically the same as the decrease which took place between these two points during the previous period,

which was 43.56 per cent, while the actual quantities contained at both points in the second period were considerably less than they were in the earlier period.

The organic nitrogen as determined by the Kjel Dahl process increased between these two points in this period from 20.88
tons per 24 hours to 27.43 tons per 24 hours, showing an
9070 increase of 31.37 per cent, which is but little more than
one-half as much as the increase which took place between these two points in the period of three years prior to the opening of the Chicago main drainage channel. The figure for that period being an increase of 62.15 per cent.

The total nitrogen contained in the waters shows a decrease of 5.16 per cent in this period as against an increase of 7.47 per cent during the earlier period.

The albuminoid ammonia shows an increase of 25.03 per cent as against an increase of 44.39 per cent during the earlier period, the oxygen consumed showing an increase of 27.68 per cent as against the increase of 45 per cent during the earlier period.

The data of this table No. 15 of this series show that the condition of the water of the Illinois river just above Peoria is very much better since the opening of the Chicago main drainage channel.

The data of this table No. 15 of this series corresponds completely with the data of the various tables I have introduced in evidence, in showing that the condition of the water of the Illinois river just above Peoria is very much better since the
opening of the Chicago main drainage channel, and that
9071 the natural destruction of the organic matters discharged
into the river in the sewage is by the time the water reaches Averyville, is far more complete than it was at this point prior to the year 1900.

A comparison of the data for Kampsville with those at Averyville shows that at the like periods which have been referred to (and no examinations of the water at Averyville were made in 1902,)—the actual weights of nitrites and of free ammonia carried by the water of the Illinois, decreased more than 40 per cent during the flow from Averyville to Kampsville; inasmuch as the waters of the tributaries of the Illinois contained organic material in proportions equal to those of the Illinois itself, and since enormous quantities of nitrogenous organic matters are discharged into the Illinois at Peoria and Pekin, a few miles below Averyville, a considerable increase in the quantities of nitrogenous organic matters in the waters of the lower Illinois might well be expected, but it is to be remembered that the organic matters in the waters of the Illinois below Havana, 45 miles below Peoria and 88 miles above Kampsville, consist of vegetable matters chiefly those of the plankton, as is shown both by observation and by the results of the general investigations which have been introduced in evidence.

9072 Q. Professor, in your testimony in reference to the pollution of the Illinois river by reason of the sewage of Peoria, and the deposits in the river of the matters from the distilleries, you stated that at the time that you desired to make some corrections subsequently as to the amount of organic matters deposited by reason of these distilleries and the cattle fed there. Will you now make that correction?

A. I made a statement that the number of cattle fed at the distilleries and in the stock yards at Peoria and Pekin were 40,000 annually. While this was true of previous times, for previous years, the number have in late years been reduced, and I understand that there are now being fed in the distillery sheds at Peoria and Pekin but 18,000 head of cattle annually.

One other correction I wish to make, with respect to the amount of corn used in the glucose works at Geneva, from which discharges of organic matters are made into the Fox River. I stated that 40,000 car-loads of corn per annum were used in these works, while the correct amount, according to my information is 30,000 carloads of corn per annum, averaging 40,000 pounds of corn per car.

Q. Professor, before you conclude your testimony I wish you would define, for the benefit of those who may read
9073 this record who are not chemists or sanitary experts, some of the words and phrases which have been so frequently used in the testimony in this case. In giving your definitions, please avoid as far as possible the use of technical terms and make it as plain as possible, what the words and phrases mean, and first will you define what is meant by the words "organic matters in water"?

A. By the term "Organic matters" I mean such matters containing carbon in combination as constitute the tissues of living things or organisms, and as are contained in the various secretions or liquids contained in living things of all sorts, great and small, and some of the products elaborated by living organisms, excreted by them, or built up into their tissues, excluding the carbon di-oxide, which is excreted by certain living organisms, and absorbed and utilized by other living organisms, but which is commonly regarded as mineral or inorganic substance.

Q. What is the meaning of the words "nitrogenous organic matters in water"?

A. By the term "Nitrogenous organic matter" we mean to designate those organic matters which contain the element nitrogen as an essential constituent. Not all organic matters
9074 contain this element, but the tissues of living things all
contain or in part consist of, organic matters of which nitrogen is an essential element. Such matters as the substance or flesh, the proteate bodies, stirred up in the seeds of plants known as gluten and so on, and other substances contained in the juices and secretions of living organisms, which are organic in character, and which contain nitrogen as an essential constituent. There are certain nitrogenous organic matters secreted by plants and animals of which the best example perhaps is, the urea excreted by animals in the urine, which contribute in partial proportion to the nitrogenous organic matters contained in sewage.

Q. What is meant by the term "oxidation" used in the consideration of the organic matters in water?

A. By the term "oxidation" I mean the combining or uniting of oxygen with the various organic matters contained in the water, and in a general way also, the union of the elements of water possibly, with these organic matters which latter is frequently called hydrlosis. The effect of this oxidation being in general to convert the organic matters into substances which are regarded as inorganic or mineral in character.

Q. What agencies produce oxidation in water?

9075 A. The chief agencies in bringing about oxidation of
organic matters in sewage are the living organisms present in the water, particularly those of the minuter forms, and which are commonly referred to as bacteria.

Q. How do these bacteria effect or produce oxidation?

A. I don't know.

Q. What is meant by the term "nitrification" as used in this investigation?

A. By the term "nitrification" as I have used it in my testimony I understand such oxidation of the nitrogenous organic matters contained in the water as results in the conversion of the nitrogen of these matters into nitrite and nitrates; that is, essentially finally into saltpeter and nitre. Complete conversion of the nitrogenous organic matters that have undergone nitrification into mineral substances which comparatively are innocuous.

Q. What is meant by the words "turbidity" in water, and what by the word "color," and what is the distinction between turbidity and color in water?

A. The turbidity of water is due to or consists in a certain appearance of cloudiness and partial opacity, which result from the water containing matters in suspension. The color of the
water is distinguished from turbidity in that it results
9076 from the presence of colored matters in solution. A
water may be quite clear and transparent, but have a decided color, and it may on the other hand be both turbid and colored. One is not necessarily associated with the other. Suspended matters which make a water turbid, may impart also a color to the water, but such color is removed by such filtration as takes out these suspended matters.

Q. Will you explain what is meant by the words "total solids", "residue on evaporation" and by loss on ignition", and what significance do you attach to the ascertainment of these factors?

A. By total solids we mean all solid matters which are contained in solution and in suspension in the water, which matters are generally determined together as total solids, by evaporating a measured portion of the water to dryness, so that the water itself is expelled. The residue thus obtained is designated as the residue on evaporation or the total solids. By loss on ignition we mean the loss in weight which takes place when the total solids or residue on evaporation is gently ignited, that is, heated to dull redness, the loss resulting from this ignition is due to the partial burning away of organic matters, and to the

loss of certain inorganic substances, and to the volatiliz-
9077 ation of certain inorganic substances or constituents of
the residue. No very great significance attaches to the loss on ignition today for the reason that it is not practicable to distinguish accurately between such loss, as due to the destruction and removal of organic matters from the loss of inorganic constituents as water, carbon-di-oxide, oxygen from nitrates, salts of ammonia and so on. The significance attaching to the determination of total solids or residue on evaporation, lies in the fact that too great a quantity of such matters contained in water render it unsuitable for domestic use or for manufacturing or steam making purposes.

Q. What does the presence of chlorine in water indicate?

A. Chlorine is contained in the soils in some proportion, but it is a considerable constituent of sewage and of manufacturing wastes. As contained in the water, it may be derived from one or all of these sources. The quantity contained in spring waters, is generally far less than the quantity contained in the waters of deep or artesian wells. The significance which attaches to the proportion of chlorine in the water, depends upon the source of the chlorine, the chlorine itself in such proportions
as are found in ordinary waters is not objectionable. The
9078 proportion in sea water is so great as to render such
water unfit for domestic use. The proportions of chlorine contained in the water of many deep wells is so great as to render the water saline in taste, and to render such water unfit for use for drinking or industrial purposes. It is to be understood in my statements covering chlorine, that it is chlorine in combination with basic matters and not the free substances or element that is referred to, as existing in these waters, that is, in general, it is in the form of sodium chloride, otherwise known as common salt.

Does the presence of chlorine indicate at times the presence of sewage, or might it not indicate the fact that sewage has previously existed, but has now departed?

A. The presence of chlorides in the water is frequently an index to the quantity of sewage that the water does or has contained, but no inference concerning the quantity of sewage contained in the water can be had from a determination of the quantity of chlorine, the chlorides contained, unless other information regarding the water in question previous and subsequent to the introduction of the sewage, is in hand.

Q. What is the meaning of the words "oxygen consumed" and what is the significance of such oxygen in the chemical tables to which you have testified,

9079 A. By the term "oxygen consumed" we mean the quantity of oxygen that the substances contained in the water absorb or unite with in the chemical process used in making this determination. The quantity of oxygen consumed is an index to the quantity of organic matters contained in the water, and affords information concerning the character or, I might say, in some measure affords information concerning the character of the organic matters contained, that is, some organic matters required more, or combined with more oxygen under conditions of the determination than do others. If a considerable quantity of oxygen is required or consumed by the substances contained in a given water, the reasonable inference is that a considerable quantity of organic matters is contained. If on the other hand a small quantity of oxygen is required or consumed by the substances in a given water, the reasonable inference is that the quantity of organic matters contained in that water is correspondingly small.

Q. In the table of chemical analyses to which you have testified in this case, there is an ascertainment designated as "nitrogen as free ammonia, as albuminoid ammonia, as nitrites, as nitrates, and total organic." Will you explain what is meant by each of these designations and what significance you
9080 attach to each of them in ascertaining the quality of water?

A. In my testimony I have already stated what is meant by the term "nitrogenous organic matter." The term "total organic nitrogen" designates the nitrogen contained in combination in the nitrogenous organic matters. It is determined by the Kjel Dahl process, described in my testimony with reference to methods of analysis, and is to be distinguished from the nitrogen contained in the form of free ammonia, that contained in the form of nitrites, and that contained in the form of nitrates, which are regarded as nitrogenous substances, and is also to be distinguisshed from that designated as nitrogen as albuminoid ammonia, although it includes the nitrogen of the latter. It is usually from two to three times greater than the nitrogen as albuminoid ammonia so-called. The nitrogen as albuminoid ammonia is derived from the substances which are designated as nitrogenous organic matter, but the nitrogen which, in the process of chemical examination, is determined under the name of nitrogen as albuminoid ammonia is only part of the nitrogen contained in the organic matters.

ADJOURNED until 2:00 P. M. same day, Friday, November 20, 1903.

9081 2:00 p. m., Friday, November 20th, 1903. Continuation pursuant to adjournment.

Present, the Commissioner and same counsel representing the respective parties.

PROF. ARTHUR W. PALMER,

resumed the stand for further direct-examination, by Judge Springer, and testified as follows:

Q. Professor, will you proceed with your explanation of nitrogen as free ammonia?

A. Nitrogen as free or saline ammonia as recorded in the results of the sanitary chemical water analyses, is the quantity of nitrogen contained in the water in the salts of ammonia or possibly as free ammonia, and as contained in water, is derived from various sources. The rain in falling through the air washes from it small quantities of nitrogen in the form of ammonia, or ammonia salts, and at times the proportion of ammonia and ammonia salts so introduced into water, may be considerable.

It is also derived from the soil or earth with which water comes in contact on its way to the streams, and is derived also from waste organic matters either of vegetable or of 9082 animal origin which may be upon or in the soil and earth with which the waters on their way to the streams in times of fall of rain or the melting of snows, come in contact.

It is also derived from the decomposition of various nitrogenous organic matters which I have described above, both those which are contained in the vegetation, that is, the leaves and stems of grasses, and other plants; of trees, waste vegetable products and waste animal matters of various descriptions, and also from the nitrogenous organic matters contained in sewage and in manufacturing wastes of various descriptions.

It is also produced at times by the reduction of nitrites when these are in contact with decomposing organic matters, when these all are wet or contained in water. The significance which attaches to the presence of free ammonia in a water depends upon the source from whch it has been derived. The ammonia in itself in the proportions in which it is contained in waters is not objectionable, but inasmuch as the free or saline ammonia is a considerable constituent of sewage, the conditions under which it is introduced into or produced in or continues to exist in a given water, must be fully understood and considered in determining its significance in the particular case.

Q. You may proceed with nitrites and nitrates?

9083 A. Nitrogen as nitrites as recorded in the results of the sanitary chemical water analyses refer to the nitrogen contained in combination with oxygen and other substances and constituting salts, which are called nitrites. They are derived in part from the air, being washed from the air usually in the form of nitrites of ammonia by falling rain. They are also derived from the leechings of soils and earth strata with which the fallen rain on its way to the streams comes in contact. They are formed, moreover, in the oxidation of the various nitrogenous organic matters which have been referred to above in my testimony, both those lying upon the surface of the ground or contained in surface soils, in the streets, in barn-yards, in the fields, and from similar changes taking place in the nitrogenous organic matters contained in the water of streams and lakes and ponds; both those derived from or contained in nitrogenous vegetable matters of all descriptions and nitrogenous animal matters, such as are contained in the wastes of habitation, including sewage, barnyard wastes and various manufacturing wastes.

They are also formed by the oxidation of the free or saline ammonia above referred to, as well as by the reduction of nitrates.

9084 The significance of the proportion of nitrites contained in a water depends upon the origin and the amount of the nitrites and the conditions prevailing at the place and time and in the body of water in which they are found.

Nitrogen as nitrates, as recorded in the results of the sanitary chemical analyses of water, represents the quantity of nitrogen that is in combination with basic matters and oxygen, the latter in greater proportion than is contained in the nitrites above referred to. The nitrates, like free ammonia, and nitrites are at times derived in part from the air, being washed from the air by rain and so carried to the earth. They are derived also from the earth strata with which the rain comes in contact and over which or through which it flows on its way to the streams or into the great body of ground water.

The nitrates are derived from the oxidation of the nitrogenous organic matters repeatedly referred to in my testimony above, to the oxidation of free ammonia and to the oxidation of nitrites, both in soil strata and in the water itself. The nitrates constitute the chief final nitrogen containing product of the oxidation of nitrogenous matters of various descriptions, including the nitrogenous organic matters.

9085 A portion of the nitrogen contained in all these various nitrogenous matters, organic and inorganic, is often separated in the form of free nitrogen gas, which may remain in solution in the water or escape from the water and mingle with the air, but generally the major part of the nitrogen of the various nitrogenous matters above referred to is oxidized finally to nitrates.

Nitrates are generally found in notable quantity in the waters of wells, of considerable depth, the so-called shallow wells, and is frequently found in the water of deep wells. It is commonly found in the waters of springs, and is rarely, if at all, absent from surface waters.

It is formed in the oxidation of all sorts of nitrogenous organic matters, both those which are derived from natural vegetation and animal matters, as also from the wastes of habitation, including barnyard refuse, street washings, sewage, and so on.

The significance of the nitrates contained in water depends upon the source and quantity of the nitrates and the conditions under which it has been introduced into or produced in and continues to exist in, the given water.

9086 It is to be noted that the nitrogen passes through a series of conditions, or a cycle of transformations the starting point in which may be regarded as any one of the stages or any one of the conditions or combinations described above, in which it exists in waters. If we consider the nitrogenous organic matters as the first condition or combination in which the nitrogen exists, we may consider the nitrogen in the form of free ammonia as marking the next step or stage in the cycle, this free ammonia being produced in the decomposition or the breaking down of the nitrogenous organic matters, the result of this decomposition being to bring the nitrogen into a sort of combination, namely, the free or saline ammonia, which in the proportions found in water, is not in itself injurious or objectionable.

Following upon the transformation of the nitrogenous organic matters, and the conversion of the nitrogen from organic combination to the inorganic form of free or saline ammonia, the next step in the stage or cycle may be regarded as the partial oxidation of the free ammonia into nitrites which thus constitute the second stage in the series of transformations. The nitrites in turn by further oxidation are converted into nitrates, a comparatively stable form of combination usually regarded as the final stage of oxidation of nitrogenous matters, but the
9087 nitrates are utilized by living organisms, that is, plant life, as a food stuff, and the nitrogen of the nitrates built up into the substance of the plant, that is, converted again into the tissues, and so on, thus being converted into the nitrogenous organic substances of the plant, which nitrogenous organic substances either directly or after digestion and assimilation by animals and conversion into the tissues and secretions of animals may, when in contact with or contained in waters, enter again upon the same series of transformation we have just briefly discussed.

Q. Professor, is it possible to form a reasonably accurate judgment of the condition of a given water from consideration of any one constituent determined in the sanitary chemical analysis?

MR. JEFFRIES: I object to the question for the reason that the word "conditon" is used in its general sense in the question and not with reference to the sanitary condition of the water.

A. No resonably fair judgment regarding the sanitary condition or the potability of a water can ordinarily be drawn from the consideration of any one single constituent determined in the sanitary chemical analysis of a water, but all must be considered together, and with full knowledge of the source of
9088 the water, and of the substances contained in it, and the conditions of time and place and environment, season, and so on.

Q. Professor, tables Nos. 13 and 14 and the tables representing the average monthly flow of the water in the Illinois river, which you read in evidence this morning, show that a greater volume of water passed over the Kampsville dam for the period prior to the opening of the Chicago drainage canal than for the period since that time. What is your explanation of this fact?

MR. JEFFRIES: I object to the witness making any explanation based on the question submitted and growing out of tables 13 and 14, so marked, A. W. P., introduced and read in evidence this morning, for the reason as stated by this witness that the chemical constituents named in those tables and upon which the computation is made, are so uncertain, changeable and unreliable as to give any proper conception of the comparative volumes of water flowing over Kampsville dam during the years in question; this objection being also based upon the definition description and characteristics stated in evidence by this witness with reference to the chemical constituents of nitrogen as nitrites, nitrates, free ammonia, Kjel Dahl organic nitrogen, total nitrogen, albuminoid ammonia and oxygen consumed; and
9089 for the further reason that in these tables the witness has not taken into consideraton the amounts of these chemical constituents that have been drawn into the river from the air, from the rain and from other sources as stated by him; and also for the reason that by the tables no consideration is given the influence of the greater amount of vegetation in the Illinois river prior to the opening of the canal as compared to its condition subsequent to the opening, as shown by defendants' testimony in this case.

JUDGE SPRINGER: The objection of counsel relates to the weight of the testimony and not to its admissibility.

MR. JEFFRIES: I suggest to the court that it is not a question of weight at all. This witness by his definitions of these terms, and by describing their characteristics in water, their appearance and disappearance, has disqualified, and made totally unreliable any conclusions of the character called for in this question.

JUDGE SPRINGER: I suggest that counsel's comments are based upon chemical analyses and tables which can only be correctly interpreted by an expert on water analyses, and he has not qualified to pass judgment as such. We will submit those questions to the court.

MR. JEFFRIES: I suggest that it does not take an expert to understand the definitions of the various chemical 9090 terms described by this witness, and which Judge Springer requested in his question very specifically, that the witness so state and define these terms that a layman may understand them, and believing that I understand the definitions and the description and characteristics of these constituents, as stated by this witness, I again state that from the definitions and characteristics stated by him the testimony is irrelevant, incompetent and misleading, and therefore is of no value so far as the issues in this case are concerned, or so far as the determination of the volume of water passing over the Kampsville dam during the two periods in question, is concerned.

JUDGE SPRINGER: Counsel for defendants regrets that counsel for the complainant has so far failed to understand the definitions given in the testimony of this witness as to make him still incompetent to pass upon the values of chemical analyses of water, and these are questions which must be submitted to the court, and the counsel's objection is merely argumentative.

Q. (Question repeated.)

A. The fact as set forth in my testimony of this morning, relating to the mean monthly flow of water in the Illinois river at Kampsville during the years 1897 to 1902, inclusive, which 9091 showed that at times during the later period, that is, the three years after the opening of the sanitary canal, or Chicago main drainage channel, a smaller volume of water was discharged than was discharged at times during the earlier period, and that the mean or average daily flow during the three years subsequent to the opening of the sanitary canal was slightly less than the mean daily flow during the three years period prior thereto, was due to the fact that in the years 1897 and 1898, the rainfall was considerably greater than it was during the years 1900 and 1901.

The year 1899 was a year of drought and the rainfall during that year was deficient, that is, below the normal, and the flow in the river at Kampsville was very considerably less than it had been during the years 1898 and 1897. In the following year, the year 1900, the drought continued, but there was increased flow in the Illinois river at Kampsville due to the increased discharge of liquid, that is, water and sewage, from Chicago through the Illinois and Michigan canal and the main drainage channel.

The year 1901 was a year of severe drought, deficient rain fall, high temperature and dry winds, and the flow in the river during this year was practically the same as the flow during the year 1899, the year immedately prior to the opening of the main drainage channel. On the other hand, the year 1902 9092 was a year of exceptionally great flow, that is, the greatest flow during the six years here in question was that for the year 1902.

The average for the three year period, because of these variations in the rainfall for the various years was, on the whole a little less than the average for the three years prior to the opening of the main drainage channel.

Q. Professor, wherein does the real value of your data concerning the composition of the waters of the Illinois river before and after the opening of the Chicago Drainage Canal lie?

A. Touching the questions at issue in this case, the real value of the evidence which I have introduced in this case in the way of analytical data lies in the comparison which it institutes between the period prior to the opening of the Chicago main drainage channel and the period subsequent to that opening. For the reason that the various determinations so far as they themselves were concerned, and including the collections of the samples, were made under precisely the same conditions throughout both periods, and that they afford data which are strictly comparable, and which show the conditions pre-9093 vailing in the waters of the streams in question before and after the great change which was co-incident with and produced by the opening of the Chicago main drainage channel.

MR. JEFFRIES: I move to strike out the answer of witness because it is a comment on the evidence. It is for the Court to determine the real value and not the witness.

Q. JUDGE SPRINGER: Professor, you have made numerous examinations of the water of the Illinois river at Kampsville, 30 miles above the mouth of the river. Does Kampsville afford a better opportunity for determining the real character of the water of the Illinois river which is discharged into the Mississippi river than does Grafton, which is at the mouth of the river?

A. The conditons which prevail at the mouth of the Illinois river at Grafton are such that at times water from the Mississippi backs up into the Illinois, and fluctuations in the height of the water in the Mississippi, and indeed, in the Missouri, produce fluctuations in the Illinois below Grafton. For these reasons, and because it was practicable to secure the services of most intelligent collectors, namely, the Assistant United States Engineers who were in charge of the improvements on the lower Illinois, and in residence at the Kampsville dam, Kampsville is the best place on the lower Illinois, near the mouth, 9094
to obtain, samples which should truly represent the character of the water of the Illinois river as it is about to discharge into the Mississippi.

MR. JEFFRIES: I move to strike out what the witness says with reference to the collection of samples by the engineer in charge of the government works at Kampsville, for the reason that the testimony of this witness shows that he did not personally take but two or three of the samples collected at that point.

JUDGE SPRINGER: The objection is not valid for the reason that it is merely a comment on the weight of the testimony and does not go to its admissibility. The testimony heretofore given states exactly how the samples were obtained and the record will speak for itself upon that subject.

MR. JEFFRIES: In consonance with Judge Springer's last remark I move to strike out all that the witness has said with reference to the taking of the samples, for the reason that the testimony of the sample takers themselves shows how the samples were taken, and what the witness says in respect to that is merely a comment on the manner of taking the samples.

JUDGE SPRINGER: The testimony of the sample takers is also in evidence and will speak for itself.

9095 Q. Professor, are you acquainted with the conditions which exist in the water-shed of the Illinois river at this time, and with the conditions which have existed during the past ten years, and especially with the conditions which have existed on the Illinois river and the region near the stream?

A. I have lived upon the watershed of the Illinois river for about 36 years. During a portion of that time living on the banks of the Fox river, one of the chief tributaries of the upper Illinois, and I have been fairly familiar with the conditions prevailing upon the watershed of the Illinois river and with the conditions along the stream itself during the last ten years, and am familiar with the conditions prevailing along that stream and upon much of its watershed today.

Q. Taking into consideration the conditions which exist upon the watershed of the Illinois river, and also the numerous chemical analyses of the waters of the Illinois river which you have made and about which you have testified in this case, what effect in your opinion, has the opening of the Chicago drainage canal in January, 1900, had upon the waters of the Illinois river, and especially upon those waters at Averyville, just above Peoria, and at Kampsville near the mouth of the river, and at Grafton?

9096 A. Taking into consideration my knowledge and information concerning the Illinois river, its tributaries, its watershed, and the conditions prevailing upon and along the same, and taking into consideration the chemical examinations that I have made of the waters of the stream and its various tributaries, both before and after the opening of the Chicago main drainage channel, it is my opinion that the effect of the greater discharge of water resulting from the operation of the Chicago main drainage channel, has greatly improved the condition of the water of the Illinois river all along its course, rendering its waters less offensive to the senses in the immediate neighborhood of the point of discharge of Chicago's sewage into the Desplaines and thence into the Illinois, and reducing the propor-

tions of the organic matters contained in the waters of this stream at Averyville and at other points along its course, and reducing the proportions of nitrogen as free ammonia and as nitrates, and reducing also the quantities of nitrogen as ammonia and as nitrites contained in these waters, and in reducing not simply the proportions, but reducing also the actual quantities of the nitrogenous organic matters contained in the waters of this stream at various points, and particularly at Averyville, to all of which I have testified heretofore, in the evidence
9097 I have presented in this case; and with respect to Kampsville I may refer to my testimony given above in this case, and state it as my opinion here, based upon the considerations enumerated above, that the condition of the water at Kampsville has been greatly improved co-incident with and as a consequence of the operation of the Chicago main drainage channel, in that my evidence shows a great reduction in both the proportions and the actual quantities of the most significant constituents of these waters as determined by the sanitary chemical analyses. And I base this opinion further upon the fact that since the opening of the Chicago main drainage channel, or sanitary canal, although the quantities of organic matters in the sewage now discharged into the Desplaines and thence into the Illinois river, are 30 per cent. greater than before that opening, the proportions of organic matters contained in the waters discharged by the Illinois river into the Mississippi are considerably smaller than they were prior to 1900; and that this decrease of the proportions is not a mere dilution is shown by the fact testified to by me, that the actual quantities of organic matters discharged are now less than they were formerly.

Q. Professor, are you acquainted with the conditions at the mouth of the Illinois river, and at the mouth of the Missouri river, and the conditions which prevail at the place called
9098 the chain of rocks in the Mississippi river, where the St. Louis intake is located, in reference to the water supplies at those points?

A. I have visited these points repeatedly and am somewhat familiar with the state of affairs there, the way the rivers come together, and so on.

Q. From your knowledge of this subject and from your knowledge based upon the numerous investigations which you have made, and about which you have testified in this case, what is your opinion as to the suitablity of the waters of the Illinois river at its mouth, the Mississippi river just above the mouth of the Illinois river, and of the waters of the Missouri river just before they enter the Mississippi river, for domestic purposes, and especially for use for drinking purposes?

9099 A. From a consideration of my knowledge and information concerning these bodies of water, and a consideration of the results of investigations I have made of these waters, and the study of investigations made by others of these same waters, it is my opinion that neither the water of the Illinois river at its mouth, nor that of the Mississippi river just above the mouth of the Illinois river, nor that of the Missouri river just above its mouth, is suitable for domestic use; that is, particularly for drinking purposes without filtering, or without such treatment as shall render it sterile as by boiling or other means.

MR. JEFFRIES: I move to strike out all that the witness said with reference to the Missouri and Mississippi river waters, for the reason that it is immaterial and has no bearing upon the issues of this case. We are not dealing wth the sanitary condition of the water in the Mississippi river above Grafton, or the Missouri river, and so far as the issues here involved are concerned, it matter not whether they are in a sanitary condition or not.

JUDGE SPRINGER: Professor, from your knowledge of
the conditions of the Illinois river and the watershed of that
river and of the flow of the water in the river, the seasonal
9100 changes, the amount of sewage coming from the Chicago
drainage canal and from the amount of water from Lake
Michigan which enters the drainage canal and the sewage which passes through the drainage canal into the Desplaines and Illinois rivers, and from the investigations which you have made of the waters of the Illinois river both before the opening of the drainage canal and since that time, to which you have testified in this case, what effect, if any, in your opinion, has the opening of the Chicago drainage canal in 1900, had upon the waters of the Mississippi river as they flow along the eastern border of the State of Missouri, and has the opening of the Chicago drainage canal, injuriously affected such waters so flowing along the eastern border of the State of Missouri for domestic, manufac-

turing and agricultural purposes, for use by the inhabitants living on the banks of said river in the State of Missouri?

A. From the knowledge and information which I possess concerning these waters and the conditions existing in and about them, and the results of the investigations which I have made of these waters before and after the opening of the Chicago main drainage channel and the knowledge I have of investigations of these same waters made by others before and after the opening of the Chicago main drainage channel, it is my opinion that the effect of the increased flow secured by the opening of the
9101 Chicago main drainage channel has been at times to increase the flow of water in the Mississippi river along the western borders of the state of Illinois and the eastern borders of the State of Missouri, and further it is my opinion that the increased flow secured by the opening of the Chicago main drainage channel containing as it does, increased quantities of organic matters derived from Chicago sewage, does not injuriously affect the waters of the Mississippi along the eastern borders of the State of Missouri so far as the use of such waters for domestic, agricultural and manufacturing purposes is concerned, for the reason that the effect of the increased flow secured by the opening of the Chicago main drainage channel, has been co-incident with or the cause of more complete destruction of the organic matters introduced into the upper Illinois river to such an extent that the waters discharged by the Illinois at its mouth contain less organic matters than they did prior to the opening of the Chicago main drainage channel, and further for the reason that it is my opinion that the organic matters contained in the Chicago sewage conveyed into the Illinois river by the Illinois and Michigan canal and the Chicago main drainage channel, so far as the sanitary chemical analysis can determine, are destroyed completely or converted into mineral matters and
9102 vegetable matter, which as contained in such water are practically innocuous.

Adjourned until 10:00 a. m., Saturday, November 21, 1903.

9103 10:00 A. M. Saturday, November 21st, 1903. Continuation pursuant to adjournment. Present, the Commissioner and same counsel representing the respective parties.

PROF. ARTHUR W. PALMER,

resumed the stand for

CROSS-EXAMINATION,

By Mr. Jeffries.

Q. Professor, have you ever had any experience with reference to the examination of water in any other streams than those in the State of Illinois, to which you have testified in chief?

A. With the exception of some samples from the Ohio river and the Mississippi and the Missouri rivers, and a few from the Wabash between Indiana and Illinois. Mr. Jeffries does that include other river waters in Illinois?

Q. No sir.

A. I have examined others besides those testified to.

Q. And your connection with the rivers of the State of Illinois began about when?

A. As a student I did a little work that didn't amount to much, in the years 1880 to 1883, but somewhat system-
9104 atic work was done by me with respect to river waters
in the summer of 1894. I had examined the waters of several streams in the state before that, in 1890 to 1894, though in a small way at that time.

Q. Was anybody else engaged with you in your work, or was anyone other than you engaged in this work in the State of Illinois under the statute which you have read in evidence and which was passed by the Legislature of Illinois in about 1897?

A. No one except my assistants.

Q. And when you speak of assistants, you mean men assisting in your chemical work in connection with these rivers?

A. I do.

Q. That is the full extent of the examination of the waters of the State of Illinois with reference to obtaining their sanitary character under the act in question?

A. It is.

Q. Is it your opinion that you can ascertain the sanitary condition of the water from the analyses which you have made of the various rivers tributary to the Illinois river, and the Illinois river, and that you can obtain and have obtained accurately the sanitary condition of that water and ascertained as to whether or not the waters of those rivers contained
9105 deleterious matters or disease producing elements or organisms?

A. It is my opinion that the analyses which I have made of the waters of the streams of Illinois and to which I have testified in this case throw much light upon the sanitary condition of the waters in these streams but do not directly determine the question as to the presence or absence of disease producing organisms in said waters.

Q. Then you do not say that in these determinations you have ascertained the presence or non-presence at any time of disease producing elements or organisms?

A. I say that in my opinion I have not by my chemical investigations of these waters determined the presence or absence of disease producing organisms. I do not quite understand the meaning which you attach to the term disease producing elements.

Q. The word "elements" for the information of the witness, is used for the purpose of giving the question the broadest possible significance for sanitary purposes.

A. I still fail to discover any precise meaning attached to the word "element" in this question.

Q. State professor, whether or not in your analyses of the waters contained in the Chicago drainage canal at Lockport, or at any other place, you obtained the presence or non-
9106 presence of disease producing organisms or substances or evidence of their presence in that water?

A. My sanitary chemical analyses of the waters of the Illinois and Michigan canal, and of the Chicago main drainage channel were not such as might be expected to determine directly the presence or absence of disease producing organisms, but inasmuch as they were of such a character as to show the presence or absence of sewage, they do indicate the possible presence or absence of substances characteristic of sewage and hence, in some measure, disclose the presence or absence of deleterious substances, substances which as a class are objectionable in drinking waters, for the reason that they themselves or substances which accompany them in sewage, are deleterious to health when introduced into the system through drink.

Q. Do you know professor, and is there anything in the science of chemistry as applied to sanitation which will give you definite information as to the presence, kind and characteristics of the disease producing organisms or substances which as stated in your last answer, accompany certain chemical constituents found in water?

A. It is my opinion that the basis for the detection of
the presence and the kind and the characteristics of the
9107 disease producing organisms and substances which in
sewage and waters at times accompany the chemical constituents found in these fluids, rests mainly upon the various chemical reactions and decompositions which said organisms and substances produce and the chemical substances which result from their action.

Q. Then by your answer, professor, do I understand you to say that from the chemical analyses of the water in the Illinois river and the Chicago Drainage canal, that you can determine and have determined the presence, the kinds and the characteristics of disease producing organisms, which accompany certain chemical constituents found in those waters?

A. No; that is not what I understood and I do not wish you to understand me to say that.

Q. Then referring to my second preceding question, state if it is not a fact that you cannot determine from your chemical analyses made of the waters of the Illinois river and from the Chicago drainage canal and from those chemical analyses, you have not determined the presence, kind and characteristics of disease producing substances which accompany certain chemical constituents referred to by you in the preceding answer?

A. The sanitary chemical analyses which I have made of these waters do not directly indicate the presence or absence of disease producing substances, and I have not deter-

9108 mined directly the presence or absence of said disease producing substances in these waters.

Q. Is there anything in chemistry so far as you know, which recognizes certain disease producing organisms in water as applied to running streams?

A. In my opinion without the science of chemistry, or without a recognition of the chemical changes or the significance of the chemical changes which disease producing organisms bring about, there would be no means of determining their presence or absence in running water, but, the branch of science which is directly concerned in the utilization of chemical and other reactions for the purpose of determining the presence or absence of disease producing germs, is, in my opinion, the science of bacteriology.

Q. Do you as a chemist, aside from any other science, recognize certain organisms contained in river waters subjected to sewage pollution, which are of a disease producing character? I mean by that that the organisms referred to in the question are of a disease producing character.

A. In my opinion, I could become acquainted with said organisms, only through the application of chemical principles and facts to the study of the characteristics and reactions produced by such organisms, but it is customary to desig-
9109 nate that branch of science which applies itself directly to a study of these organisms and their reactions and characteristics and the chemical changes which they effect as bacteriology. To this branch of science I have not devoted much study, and as a chemist pure and simple, in the acceptation of that term in which the question apparently is put, I am unable to recognize disease producing organisms.

Q. Then professor, as a chemist, you do recognize the existence of disease producing organisms in water that has been subjected to sewage pollution. In other words, professor, it seems to me your answer is a little bit inconsistent.

A. As a chemist pure and simple, I do not recognize the presence or absence of disease producing organisms in water in the sense evidently meant by the question.

Q. As a chemist, do you doubt the presence of disease producing organisms or disease producing substances in waters which have been subjected to sewage pollution?

JUDGE SPRINGER: I object to the word "doubt" as used in this question, as not calling for an answer which would be properly recognized as testimony. That is to say, it neither calls for an opinion as an expert or a fact.

A. As a chemist I doubt nothing except in the light of evidence which appeals to the experience and intelligence.

9110 MR. JEFFRIES: Now, as applied to the particular substances or organisms mentioned and referred to in the proceeding questions, what do you say?

A. It is extremely difficult indeed, and I feel it to be impossible, but it is the other side, that side of me which is the chemist, as distinguished from the entire individual.

Q. As a chemist and as an individual, will you state whether or not you doubt the presence of organisms and substances of a disease producing character in the waters of a river which have been subjected to a sewage pollution?

A. As a chemist and an individual, it is my opinion that there can be no doubt but that disease producing organisms and substances are contained in sewage, and in sewage are frequently introduced into running streams.

Q. As a chemist, is it not a difficult matter to determine the quantity of such disease producing organisms and substances which may exist at any given point in a river, which has been subjected to sewage pollution above that given point, and does not the quantity of such disease producing organisms and substances, depend to a large extent upon the extent and amount of polluting substances so discharged into that
9111 river?

MR. TODD: I want to object to the question on the ground that it is improper in form and suggest to the witness that the answer can be divided, as two questions are involved in this one.

A. A chemist pure and simple, does not attempt to determine directly the presence or absence or the quantities of disease producing organisms.

Q. So then, from the standpoint of a chemist as applied to my last preceding question, the quantity of disease producing organisms and substances may be great or may be small, may they not?

A. A chemist who concerns himself with the study of running waters, their pollution and purification, the seasonal variations to which they are subject, as to content and character of various substances does recognize the fact that disease producing organisms and substances are introduced into running waters in sewage and recognize as a fact that the quantities of such disease producing substances and organisms may be greater or less at different points and at different times, although he as a chemist simply, does not ordinarily determine the quantities of such disease producing organisms or substances.

Q. Can he determine the quantity?

9112 A. Not as a chemist pure and simple.

Q. Can he determine their presence as a chemist pure and simple?

A. No.

Q. Or by the usual sanitary chemical analysis?

A. No.

Q. As a chemist, are you acquainted with the kinds of organisms and substances of a disease producing character in a river water which has been subjected to sewage pollution?

A. Not as a chemist pure and simple, if there can be such a thing, but I have some knowledge of these matters incidentally acquired in my study of the problems involved in the pollution of streams and the purification of flowing waters.

Q. Is there anything in the science of chemistry so far as you know which will determine and which does determine the kinds and character of the organisms and substances which produce disease, and which are found in river waters subjected to sewage pollution?

A. I have already answered that question substantially in my answer to an earlier question and see no reason to add to the answer there given.

Q. Is there anything in the sanitary chemical analysis of water as ordinarily conducted, which discloses the kinds and character of the disease producing substances and or-
9113 ganisms contained in polluted waters?

A. There is not.

Q. As a chemist, do you know whether or not these disease producing organisms and substances are dependent for their life and existence upon the present or absence of the various chemical constituents found in polluted waters and obtained or determined by sanitary chemical analyses of the waters?

A. It is my opinion as a chemist and an individual that the substances—

Q. Professor, we are talking chemistry now.

A. I am speaking as an individual concerning the science of chemistry. It is my opinion as a chemist and an individual that the substances, the presence and proportions of which are shown by the sanitary chemical analyses of waters as ordinarily conducted include those substances which serve as the food supply of micro-organisms, and include the substance itself of micro-organisms, both the harmless sort and the disease producing sort.

Q. Is there anything in the science of chemistry alone which enables you to form any such opinion or draw any such conclusion?

A. Yes sir.

Q. Will you please state it.

9114 A. It is this: that the results of the sanitary chemical analysis as it is ordinarily conducted, show the presence of all the nitrogenous organic matters contained in the water, and this includes all nitrogenous organic substances whether it be that of dead matter or living matter.

Q. Is there anything in the science of chemistry which discloses the kind of nitrogenous matter in water which is of a disease producing character as separate and distinct from that nitrogenous matter which is not of a disease producing character?

A. The chemistry of toxins is an exceedingly important chapter of chemistry, and so far as concerns those disease producing substances which are called toxins, chemistry does determine the character of those substances and distinguishes them from other substances which are not disease producing.

Q. Why have you not made such determinations professor with reference to the waters in the Illinois river and the drainage canal?

A. What determinations?

Q. The determinations mentioned by you in the last preceding answer?

A. Because no practicable method is known for separating from each other the substances in the proportions which are found in such waters.

9115 Q. Is it not a fact that such determinations cannot be made from the water in a running stream which has been subjected to sewage pollution?

A. It is my opinion that it is impracticable to make such determinations in the cases referred to in the last question.

Q. Then I understand you still to say that the science of chemistry does not undertake to disclose the kind and character of the disease producing substances and organisms in matter that has been subjected to sewage pollution?

A. It is my opinion that I have substantially made that statement in answer to your previous question.

Q. That is, you are still of the former opinion, that chemistry does not make any such determinations?

A. The sanitary chemical analysis of waters as ordinarily conducted, does not in my opinion make such determinations.

Q. And because of the utter impracticability of it, you have not made determinations with reference to the waters in question?

A. Because in my opinion it is utterly impracticable to determine the character and the quantities of toxins contained in the waters in question, I made no attempt to make such determinations.

Q. Professor, as a chemist, are you able to distinguish 9116 the character of the food supply of the micro-organisms which produce disease, from the character of the other nitrogenous matters or constituents in the water? In other words, are you able to distinguish those nitrogenous organic substances which are food for the micro-organisms of a disease producing character, from other nitrogenous organic substances contained in the water?

A. The chemist pure and simple, does not make the distinction between those nitrogenous organic substances which serve as a food supply for disease producing organisms and those which serve as a food supply for other micro-organisms, but he does make a distinction between those substances which serve as the food supply of micro-organisms and other nitrogenous organic substances, which do not ordinarily serve as such food supply.

ADJOURNED until 2:00 P. M. same day.

2:00 P. M., Saturday, November 21st, 1903.

9117 Continuation pursuant to adjournment.

Present, the Commissioner and same counsel representing the respective parties.

PROF. ARTHUR W. PALMER,

resumed the stand for further cross-examination by Mr. Jeffries and testified as follows:

Q. (Last question and answer repeated). That is, the chemist can determine what particular character of chemical constituents contained in the water may be used by the micro-organisms of all characters as food, and without reference to whether or not the micro-organisms contained in the water are of a disease producing character or not; is not that true?

A. The chemist can distinguish between those nitrogenous organic matters which are of an albuminous or proteid character and which serve as a food supply for the micro-organisms and other nitrogenous organic matter which are not albuminoid or proteid in character, as for instance, many of the toxins and so on, which are products of the vital processes, or rather which are or may be products of the vital processes of micro-organisms, but which are not in general, food constituents of micro-organisms.

9118 Q. Does the sanitary chemical analysis of the water enable you to make the determination which you have just spoken of?

A. It does not.

Q. Does the sanitary chemical analysis enable you to determine whether or not the disease producing organisms feed upon any of the albuminous or organic nitrogen contained in the water?

A. It does not.

Q. Is there anything in the sanitary chemical analysis of water which enables one to determine whether or not the disease producing organisms in polluted water will live longer in the presence of other organic nitrogen than in the absence of such other organic nitrogen. In other words, is there anything in the sanitary chemical analysis of a water of a polluted stream that enables one to determine as a chemist whether or not the disease producing organisms contained in that water will live longer in the presence of other constituents of sewage in the water, than in the absence of other constituents of sewage in that water?

A. Not as a chemist purely and simply.

Q. Then from the standpoint of a chemist, one is unable to determine from the sanitary chemical analysis of water, whether or not disease producing organisms contained in a polluted stream will live longer in the presence of large quantities of nitrogenous organic matter than in the absence of such
9119 nitrogenous organic matter?

A. The chemist pure and simple is unable to determine this point.

Q. Do your analyses of the water contained in the Illinois river and the drainage canal, disclose any such determination as to the longevity of the disease producing organisms in the presence or absence of other nitrogenous organic matter?

A. They do not.

Q. Do your chemical analyses of the water in the Illinois river and the drainage canal, disclose whether or not the disease producing organisms disappear with proportionate rapidity to the disappearance of the total organic matter contained in that water?

A. They do not.

Q. Do the chemical analyses which you have read in evidence in this case disclose whether or not the disease producing organisms contained in the sewage, of Chicago, disappear to any extent whatever from that water?

A. Considered merely from the standpoint of the chemist. they throw no light whatever upon this question.

Q. What chemical constituent contained in the water would most likely contain the disease producing organisms if such a determination could be made?

9120 A. The nitrogenous organic matters.

Q. Professor, have you examined the water in Lake Michigan taken from the various cribs at times when the water supply of the city of Chicago was producing abnormal typhoid fever results?

A. As to that I am uncertain and can merely refer to the fact as testified to by me heretofore, that I made a series of analyses of samples of water collected at a tap in the city, the supply for which was taken from the lake at the Four Mile Crib opposite 14th Street which data have been introduced in evidence in this case and which cover the period of years from 1897 to 1900 inclusive. I gave no testimony as to the existence or non-existence of typhoid fever in the city with respect to those determinations and cannot state definitely whether or not there were unusual numbers of typhoid cases in the city during such time.

Q. Did you examine chemically the water from Lake Michigan other than from the Four Mile Crib at any time?

A. I did not. Well, I have made other examinations of water other than from Lake Michigan, above the water supply systems of the town of Evanston, Waukegan and other towns along the lake shore, but none others than those I testified to from Chicago.

9121 Q. Professor, I will ask you to state whether or not any of the chemical analyses of the water other than from Lake Michigan from the Four Mile crib, and analyzed by you contained as much organic nitrogen as that contained in the samples of water chemically analyzed by you from the Illinois river during the same period of time?

A. I have on several occasions found greater proportions of organic nitrogen in samples of water taken other than from Lake Michigan at the places heretofore testified to by me, than I have found in numerous samples of water taken from the Illinois river at Kampsville.

Q. Is it not a fact professor, that the water analyzed by you other than from the Four Mile Crib in Lake Michigan at Chicago, did contain smaller quantities of organic nitrogen than the samples of water analyzed by you from the Illinois river at Kampsville, as a general proposition?

A. In general the waters of Lake Michigan analyzed by me contained considerably less total organic nitrogen than I found in the waters of the Illinois river at Kampsville.

Q. If the organic nitrogen contained in the waters of Lake Michigan as analyzed by you contained a certain organism which produced typhoid fever, state whether or not there is anything shown by your sanitary chemical analysis of the water of the Illinois river at Kampsville that showed that the
9122 organic nitrogen contained in the water at that point, did not contain the organisms of such disease?

A. Whether the organic nitrogen contained in the water of Lake Michigan analyzed by me, did or did not contain the micro-organisms which produce typhoid fever, I do not know but assuming it to have been present therein, it is my opinion that there is nothing in my sanitary chemical analysis of the waters of the Illinois river at Kampsville which has determined whether or not a bacillus of typhoid fever was contained in that water.

Q. Assuming professor, the presence of that character or kind of micro-organism which produces typhoid fever in both waters, and that they are present in the organic nitrogen contained in that water, and that the proportionate amount of such micro-organisms in the respective waters corresponds to the respective amounts of total organic nitrogen in these waters, how would the number or amount present in the water of Lake Michigan as analyzed by you, compare with those present and in the water as analyzed by you from Kampsville?

A. Assuming that there was the same relation between the numbers or amounts of micro-organisms mentioned in your question and the total nitrogenous organic matters con-
9123 tained in the waters at these two points, then it is my opinion that the relation the numbers said micro-organisms would have to each other would be similar to the proportions of the total nitrogenous organic matters in each of these two waters.

Q. Knowing as you do from your chemical analyses the approximate relationship existing between the two amounts of organic nitrogen in the waters of Lake Michigan as analyzed by you and those in the Illinois river at Kampsville, what would the relationship of proportionate amounts be with reference to the particular organism producing typhoid fever, as assumed in the preceding question, approximately or as a general proposition?

A. The assumptions in the question in my opinion seem to be absurd, and involve a question of mere arithmetic rather than of chemistry or experimental science, and I fail to see that any particular significance can attach to an answer, but if an answer must be had I would practically reiterate my answer to the preceding question to the effect that the proportions they would bear to each other is a mere matter of arithmetic, but they would bear to each other the same relation as do the proportions of total organic nitrogen.

MR. JEFFRIES: I move to strike out all that the witness has said with reference to the question being absurd, 9124 first, for the reason that it not for him to say, but for the Court to determine whether or not such question is absurd; second, for the further reason that the witness has made the analyses of the water of Lake Michigan and for the Illinois river for the period beginning in 1897 and down to 1900 and even later; that he has determined the total organic nitrogen contained in those waters, that he has drawn conclusions as to the sanitary condition of that water from the various chemical constituents and the witness knows or is presumed to know the relative relationship the various constituents of the waters of Lake Michigan, bear to the same chemical constituents in the waters of the Illinois river.

Q. Now professor, I ask you again to state, first approximately the relative proportions the organic nitrogen contained in the waters of Lake Michigan as analyzed by you, bear to that of the Illinois river at Kampsville, and assuming the presence of organisms producing typhoid fever in the organic nitrogen contained in the waters of Lake Michigan and of the waters of the Illinois river at Kampsville, and assuming that they appear proportionately in amounts to the proportionate amount of total organic nitrogen contained in those waters, how would the number or amount in the one case, correspond with the number or amount in the other?

9125 JUDGE SPRINGER: I move to strike out this question for the reason that the number of micro-organisms which may be found in the water are not comparable with the total organic nitrogen contained in the water; that the presence of such organisms in water is not due to the chemical constituents in water, or to the total organic nitrogen contained in water, but that their presence in water is to be attributed solely to the fact that they have been brought into the water from some human being who had the disease known as typhoid fever, and whether they were brought into the water or not depends upon whether there are typhoid fever patients present or whose dejecta have been placed in such waters.

A The average proportion of total organic nitrogen contained in the waters of Lake Michigan which I analyzed and testified to heretofore in this case, were, for the year 1897, .268 parts per million; for the year 1898 .202 parts permillion; for the year 1899-.188 parts per million, and for the year 1900-.186 parts per million; the average for the four year period being .211 parts per million. The average proportions of total organic nitrogen contained in the waters of the Illinois river at Kampsville analyzed by me during the year 1897 was 1.204; for the year 1898-.1.018; for the year 1899 it was 1.129; the average for these three years being 1.057. The average
9126 total organic nitrogen contained in the waters of the Illinois at Kampsville during the year 1900 as already testified to by me, was .904 and during the year 1901, or rather for the first nine months of the year 1901—for these determination were discontinued at the beginning of October,—in that year the proportion was .999. The average for these two years or one year and nine months being .951, which undoubtedly is higher than would be the average for the nine months of 1901, undoubtedly being higher than would be the average for the entire year if the determinations had covered the entire year. The relation of the proportions of total organic nitrogen found in the waters of Lake Michigan for the four year period, 1897 to 1900 inclusive bears to the proportion found in the waters of the Illinois at Kampsville for the period 1897 to 1899 inclusive,

are as 1 to 5. In other words, 1 for Lake Michigan, and 5 for the water at Kampsville.

Q. Now please state the comparative amounts with reference to this chemical constituent known as organic nitrogen in the waters of Lake Michigan and the Illinois river at Kampsville as shown by your analyses of those waters for the year 1900?

A. The proportions of organic nitrogen found by me in the waters of Lake Michigan for the year 1900 were .186
9127 parts per million, and the proportions found in the waters of the Illinois river at Kampsville for this year were .905 parts per million, these two numbers bearing to each other the ratio of one for the water of Lake Michigan, to 4.86 for the water at Kampsville.

Q. Now professor, assuming that in the year 1899 there were a large number of typhoid fever cases in the city of Chicago, and that in the year 1900 there were a like number of cases of typhoid fever in that city, assuming that in the year 1899 the discharges of the dejecta of those patients in Chicago reached the intake crib and were present in the water analyzed by you from the Four Mile crib during that year; and assuming that for the year 1900 the typhoid dejecta from the patients in the city of Chicago, were discharged into the sewers of that city and thence into the Chicago river, the drainage canal, and through the drainage canal discharged into the Illinois river; is there anything in the science of chemistry or in the chemical analyses which you have made of the waters of the Illinois river at Kampsville, which discloses that these typhoid fever organisms so discharged at Chicago, did not reach and are not contained in the organic matter in the waters of the Illinois river at Kampsville?

A. Granting all these assumptions, there is not.

9128 Q. Professor, during these entire series of examinations of the waters of Lake Michigan, the drainage canal and of the Illinois river, you have used the same method of analyzing, have you not?

A. I have.

Q. Do you know whether or not you used the same method that was employed by Professor Long in his determinations?

A. That I don't know.

Q. Do you know whether or not you used the same method as that used by Profesor Jordan in his chemical analyses?

A. It is my opinion that Professor Jordan and I used the same methods.

Q. Do you know whether or not you and M. Bisbee used the same method?

A. It is my opinion that in general the same methods were used by Mr. Bisbee and by myself.

Q. Why did you need to take more than a single chemical analysis of the water of the Illinois river?

JUDGE SPRINGER: Do you mean at any one place or at all places?

MR. JEFFRIES: At any one place?

A. Because of the seasonal and other variations which take place in those waters, both as to flow and as to content 9129 of the various constituents determined in the sanitary chemical analysis.

Q. Why did you need to make hundreds and even thousands of analyses of samples taken from the river at the various times and places?

A. To cover as long a period in time as was practicable, and to cover such a period as thoroughly as was practicable.

Q. Then professor, is it possible to determine precisely the chemical composition of all parts of a running stream at all times and all places in it?

A. It is not, for the reason that it is not practicable to chemically examine every drop of water in such a stream.

Q. Then is it not a fact that your results strictly speaking show nothing more than the chemical composition of some of the waters of the Illinois river and other streams at some of the places at some times and some seasons?

A. It is my opinion that my analyses give as complete evidence concerning the composition of all of the waters passing the points at which samples of said water were collected, so far as it is possible by a sanitary chemical analysis to do so, for the reason that it is not practicable to analyze at any time, much less at all times, all the water flowing past a given point in a stream, of such a stream as the Illinois and other 9130 streams referred to in my testimony introduced in this case; and I will add further that while it is always desirable to have as many analyses as is possible, and even more than the number which I made for, say the point on the Illinois river at Kampsville, practical reasons, that is, those involved in the time, labor and expense, have prevented my making more analyses of the waters at the given points during the periods covered in my testimony, and it is my opinion that the evidence which I have submitted covers the case reasonably well, and as well as similar cases have been covered at other places and by other people in the examination of the waters of running streams.

Q. May not the water of the Illinois river have been very different at other times and other places, and even at the same place at other times, than as shown from your sanitary chemical analyses of that water?

A. It is my opinion that the water of the Illinois river at Kampsville has not been at other times during the period in question materially different from the condition revealed by the analyses which I have submitted in evidence, and it is further my opinion that the data which I have submitted reveal substantially the true composition of the water of the Illinois river at this point, namely, Kampsville, during the
9131 entire period covered by the analyses, namely, the years
1897 to 1902 inclusive.

Q. May not the samples of water have been taken at the same point by the same collectors, at practically the same time, and afterwards analyzed by different chemists, and show a material difference in the chemical constituents of that water, thus revealing a rapidly changing stream, so far as chemical condition is concerned?

A. In my opinion this is quite possible, but the averages for a considerable number of analyses of samples, taken and analyzed as you have indicated, would not in my opinion be substantially different.

Q. Would the table of averages give a correct and complete representation or picture of the waters of the river at the point the samples were taken during the entire period those samples were collected and analyzed.

JUDGE SPRINGER: What tables are you referring to?

MR. JEFFRIES: I am referring to the tables of averages the witness referred to in the last preceding answer.

(Question repeated).

JUDGE SPRINGER: I object to this question for the reason that the words "representation or picture" have no definite meaning so far as the constituent elements of water are
9132 concerned.

A. It is my opinion that no table of averages would give a complete and correct representation or picture of the water in this stream at all times, and the table of averages is not intended and cannot be expected to be so any more than the table of averages of the height of man gives a complete and correct representation or picture of the heights of all men.

MR. JEFFRIES: Q. Professor, assuming that the samples of water were taken and analyzed one time per week for one entire year, from the waters of the Illinois river, and the chemical constituents so obtained from the analyses be placed upon a table of averages, how would the various ascertainments of chemical constituents compare with the table of averages as the height of all men compare with the average man?

JUDGE SPRINGER: I object to this question for the reason that any answer that possibly can be given to it would not be responsive to the issues in this case.

MR. JEFFRIES: Referring now to the tables of averages made up from the chemical analyses of the waters of the Illinois river during any of the years those waters were examined by you and the results of which you have read in evidence in this case?

JUDGE SPRINGER: I renew my objection to the post-
9133 script.

A. It is my opinion they would compare quite favorably.

MR. JEFFRIES: Professor, if one man is 40 per cent taller or forty per cent lower than the average man in stature, how would you designate in ordinary language the relationship of the one who was taller or shorter in stature than the average man? In other words, would he not be a giant or a dwarf?

JUDGE SPRINGER: I object to this question for the reason that any answer which the witness can possibly give to it would not tend to establish any of the issues involved in this case.

MR. JEFFRIES: The relevancy of this testimony will come later.

A. The one who was forty per cent shorter than the average man would probably in ordinary parlance, be designated a dwarf, and the one who was forty per cent taller than the average man would probably in ordinary parlance, be designated a giant.

Q. Assuming that Mr. Bisbee analyzed a sample of water, the companion of one which you analyzed and both of which were collected by the same man on the same day and practically at the same time, on the 6th day of September, 1899 at Kampsville, and the determination of the constituent known as total organic nitrogen as determined by Mr. Bisbee was either forty per cent less or forty per cent more than the determination made by you; would that sample of water in ordinary parlance as applied to the table of averages which you have read in evidence, represent a dwarf or a giant sample so far as that particular constituent was concerned, and would not such differences in the determination of the chemical constituents of the water, indicate and reveal an extensively changing chemical composition of the stream, and also an enormous variation in the chemical condition of the water in the stream at that point and time? 9134

JUDGE SPRINGER: I object to this question for the reason that the words dwarf or giant as applied to chemical analyses, have no significance whatever, and I object to this question for the further reason that any assumption as to the differences of these analyses in this case, rests solely in the mind of counsel, but the best evidence is the fact which is a statement from the record of the analyses themselves.

MR. JEFFRIES: I will state for the information of the witness that this assumption is based upon the tables introduced by defendants and as having been made up from the examinations of the waters of the Illinois river at Kampsville for the time in question by this witness and the witness Bisbee.

JUDGE SPRINGER: Let the record show what Mr. Bisbee's ascertainment was for the sample examined on that

9135 day, and what the ascertainment was as found by Professor Palmer.

A. So far as the designation of a sample of water as a dwarf or a giant is concerned, I may say that I attach no significance to such terms in such an application and do not as a chemist understand the same, but, with reference to the relation of the figures representing these proportions of total organic nitrogen and the samples of water in which they were found, I would state it as a matter of opinion, that no general conclusion regarding the sanitary condition of a sample of water can reasonably be based upon one determination; that is, upon the determination of one individual constituent, and comparing the entire data of the analyses of the two samples in question, I would further state it as my opinion, that there is here simply an error to which all men are liable and that the fact that the figures representing the proportions of total organic nitrogen indicated in the question are .6 and .1 respectively, do not in the light of what I have just stated, indicate any great change taking place in the water samples collected at this time and at this point.

ADJOURNED until 10:00 A. M., Monday, November 23, 1903.

10:00 A. M., Monday, November 23rd, 1903.

9136 Continuation pursuant to adjournment.

Present, the Commissioner and same counsel representing the respective parties.

PROF. ARTHUR W. PALMER,

resumed the stand for further cross-examination by Mr. Jeffries, and testified as follows:

Q. Profesor, referring to table No. 20 of the series of tables 1 to 80 inclusive, introduced and read in evidence by yourself, and to table 178, being tables introduced by defendants, and known as Defendants' tables of Streams Examinations, 1 to 196, which constitute a part of the testimony of Mr. Bisbee, we find upon comparison of these tables that during the month of September 1899, there were samples collected by the water takers at that point, and these samples are known in the evi-

dence of these water takers as companion samples, one of each of which was shipped to you and the other shipped to Mr. Bisbee, and of these samples you analyzed four, the analyses of which were made by you September 7th, September 14th, September 21st, and September 28th, and of these samples
9137 Mr. Bisbee analyzed three, to wit, September 7th, September 14th and September 21. These samples were collected on the 6th, 13th, 20th and 27th days of September, 1899. Upon your determination of the chemical constituents of those samples, you found that on September 7th to contain 1.0 of organic nitrogen; of the samples analyzed on the 14th of September, you found .84 of organic nitrogen, and of the sample analyzed on the 21st of September, you found 1.0 of organic nitrogen, and the sample examined by you on the 28th of September, you found .82 of organic nitrogen. Mr. Bisbee in his analyses found contained in the sample analyzed by him on September 7th, total organic nitrogen .60; that analyzed on the 14th of September, organic nitrogen 1.04, and that analyzed by him on the 21st day of September, total organic nitrogen .76; no analyses having been made by him of the sample collected on the 27th of September so far as organic nitrogen was concerned. All these samples were taken from the Illinois river at Kampsville. Now do not these analyses show upon comparison, a material difference with reference to the constituent known as total organic nitrogen in the waters of the Illinois river at Kampsville for the month of September, 1899, comparatively speaking?

A. They do not in my opinion show a substantial differ-
9138 ence in the content of total organic nitrogen in the water of the Illinois river at Kampsville during the month of September, 1899, for the reason that they are in my opinion, partly the result of differences in the details of the method used in the determination of the total organic nitrogen, although the method employed was in general the same in both cases, that is, in the analyses made by Mr. Bisbee and those made by myself, and for the further reason that the averages for the month, that is, the average proportion for the three analyses made by Mr. Bisbee, namely those made upon samples collected upon the 6th, the 13th and the 20th of September, 1899, re-

spectively, and those made by me upon samples collected upon the same days in the same month of 1899, which samples were collected simultaneously with those analyzed by Mr. Bisbee, for I find that the average for the three determinations made by Mr. Bisbee were .8 parts per million, the average for the three samples analyzed by me corresponding to the three examined by Mr. Bisbee, were .95, a much less difference than is indicated between certain of the individual determinations included in these six analyses.

Q. I will ask you professor, if that difference, taking the average difference between the examinations made by Professor Bisbee and those made by yourself, does not amount to 9139 18.8 per cent, counting yours as 100 per cent, or as being accurate?

A. Assuming as the basis for the calculation my own average, .95, the difference between the two averages is 15.78 per cent while taking Mr. Bisbee's average of .8 as the basis of the calculation, the difference is 18.75 per cent.

Q. Now may not these same differences of 40 per cent, 23.8 per cent and 24 per cent, have occurred, even though you had made the analyses in both instances, for the month of September, instead of having been made one by yourself and the other by Mr. Bisbee?

A. In my opinion they would not.

Q. Is it a fact that Mr. Bisbee's results are always higher or lower than yours, or do they not vary first one way and then the other?

A. So far as I am aware, they vary in both directions, some of them being higher and some of them being lower than my own.

Q. Now I will ask you professor, if it is not a fact that a comparison of the analytical results of the samples of water collected in September, 1899 at Kampsville an examined by yourself and by Professor Bisbee, do not show either a very rapid change in the chemical condition of that water or do not show extensive variations, chemically speaking, in the water at that time and place, and even on the dates and at the 9140 hour of collecting the samples?

A. In my opinion these variations in the results of the analyses do not indicate similarly considerable variations in the actual content of the total organic nitrogen in the water samples collected at the same date and hour, nor do they show rapid variations in these substances contained in the water, but in my opinion the variations in the determinations as recorded in the tables you have quoted, are very largely the result of differences in the details of the method employed in making these determinations to which I have referred in my answer to the preceding question.

Q. Do those variations, to wit, variations comparatively speaking, shown between the analyses made by yourself and those made by Mr. Bisbee, result from differences in accuracies or differences in inaccuracies?

A. Doubtless they are in part due to both, but in my opinion in the main they are due to variations in the details of the processes to which I have referred in my answers to the two preceding questions.

Q. Professor, in laboratory experiments, is not chemistry an exact science?

JUDGE SPRINGER: What do you mean by the words "exact science" in this connection?

9141 MR. JEFFRIES: I mean by the words "exact science" that when a certain quantity of various substances have been compounded that chemistry can detect to a certainty the quantity of each of the different constituents in the compound.

A. In many cases the methods of chemical analyses do afford a means of determining accurately the proportions of chemical constituents contained in various mixtures, but whether chemistry as applied to methods of chemical analyses may be defined as an exact science, is a question which is somewhat beyond me. I have been told by mathematicians and physicists at times, that chemistry is not an exact science. Undoubtedly it is not in my opinion, capable of such exactness as are the various processes of mathematics.

Q. It is not a mathematical science is it, professor, that is, in the sense that averages can be used with any degree of certainty based upon the results obtained from a given series of analyses?

A. It is my opinion that the averages based upon a given

series of chemical determinations afford as accurate a basis for comparison and for determination of certain facts, as do the averages computed concerning the height of man, in the determination of the heights of man, or as the averages of the length of life of individual man, and of individuals of a
9142 certain class of men computed by the actuaries of insurance companies, which afford a substantially accurate basis for the determination of the length of life of individual man and classes of men, and thus afford a reasonably accurate basis for conducting the business of life insurace.

Q. Tables of averages as used by life insurance companies are based upon mathematical accuracies, are they not, or mathematically accurate data?

A. They are in my opinion based upon data which are probably mathematically accurate, for the number of individuals which it has been practicable to consider, but in my opinion in no case do they cover all of the individuals in a given class.

Q. Have you had any experience as an actuary in the insurace business?

A. I have not.

Q. So that what you say on that subject is merely an opinion based upon general business information?

A. General business information and information given to me by life insurace agents.

Q. Professor, is it not a fact that if two given quantities of water are taken from the same source at the same time, in the same manner, and analyzed practically at the same time by different analysis, that the results of total organic nitro-
9143 gen contained in that water, should be practically the same, speaking now as a chemist pure and simple, and based upon the experience of chemists in the laboratory?

A. That depends particularly upon the source from which the water samples have been taken, and largely upon the methods employed in the determination of the total organic nitrogen and all the details of the methods, and of course too, in part upon the accuracies and inaccuracies involved in the methods employed, including those of the individuals employing them.

Q. Is it not a fact professor, that yourself, Professor Long, Professor Bisbee, and Professor Jordan had a meeting before the investigations began, in which you discussed and finally determined the manner in which the samples of water should be taken and the method which should be used in making the chemical analyses of those waters, in order that the manner of collecting the samples and the manner of making the chemical analyses should be uniform with reference to all persons making those analyses?

A. It is not.

Q. Did you have any such meeting with anyone?

A. I did.

Q. Who were they?

A. Professor Jordan and Dr. Gehrmann, director of the 9144 municipal laboratory of the City of Chicago.

Q. You and Professor Jordan then, so far as the chemical examination goes, used the same system and the same method?

A. We did.

Q. Was it not your understanding at the time, that Mr. Bisbee was to use the same method?

MR. TODD: I object to what his understanding is unless he has definite information from Mr. Bisbee as to what methods Mr. Bisbee was to pursue, as his understanding is not material to the inquiry in this case. What this man's mental phenomena is as to understanding, is not a matter material in this case, whatever Bisbee's testimony would be.

Q. (Question repeated).

A. It was my understanding at the time that the methods to be used in the three laboratories, namely, the laboratory of Professor Jordan, at the University of Chicago; the municipal laboratory in the City Hall, Chicago, and my own laboratory at the University of Illinois, were to be the same, but at that time I did not know who was to do the chemical work in the municipal laboratory, whether it should be Mr. Bisbee, or anybody else.

Q. Now professor, if the same methods were used, and 9145 if the water on the 6th day of September, 1899, collected by the water taker at Kampsville, was the same and in equal parts, was forwarded to the three laboratories which you have mentioned in your last preceding answer, and the variation in the chemical analyses with reference to the ingredient or constituent known as total organic nitrogen should be 40 per cent, more or less, as determined by Professor Bisbee, than as determined by yourself, is it not a fact that an inaccurate determination was made in one instance or the other, and if no inaccuracies with réference to this constituent, is it not a fact that the sample of water which you examined contained more or contained less of the total organic nitrogen than the sample examined by Mr. Bisbee?

A. If we were to assume that there were no inaccuracies in the details of the methods employed in making the determination of the total organic nitrogen in these two samples collected at the same point, at the same time and analyzed, the one by Mr. Bisbee, the other by myself, then the results of said analyses would indicate a difference in content of total organic nitrogen as between the two original samples, but as I have stated in my answers to the three or four preceeding questions, in my opinion, the variations in the details of the methods employed in making the determination of total organic nitrogen
9146 in these two cases is mainly accountable for the differences which appear in the record.

Q. Then what you have stated with reference to the variation between the analyses with reference to total organic nitrogen as determined by yourself on the 6th day of September, 1899, from the sample of water collected at Kampsville, as compared to a companion sample collected at the same time by the same collector, and analyzed by Professor Bisbee, which shows a variation of 40 per cent, the same answer is applicable to the sample collected on the 13th day of September, which shows a variation of 23.8 per cent, is it not?

A. In my opinion it is.

Q. And the same is also true with the sample collected on the 20th day of September, which shows a variation of 24 per cent?

A. It is.

Q. And the same is also true with reference to the sample collected on the 11th of October, which shows a variation of 5.5 per cent?

A. It is.

Q. And also with reference to the sample collected on the 18th day of October, which shows a variation of 9.2 per cent?

A. Yes, and in my opinion to all the others included in
9147 these records.

Q. That is, it applies to the sample collected on the 25th day of September, 1899, at the same point, which shows a variation of 3.7 per cent; and to the one collected November 1st of the same year, at the same place, which shows a variation of 15.6 per cent, and to the one collected on the 8th day of November of the same year at the same place, which shows a variation of 90.9 per cent, to the one collected on the 22nd day of November, which shows a variation of 9.1 per cent of total organic nitrogen contained in those samples so analyzed by yourself and Mr. Bisbee, all of these calculations with reference to the percentage in comparing the analyses of total organic nitrogen, as determined by Mr. Bisbee and Professor Palmer are based upon the premises that Professor Palmer's determinations should be 100 per cent of the total organic nitrogen contained in the samples of water, and examined at these several times?

A. In most the cases you have mentioned, there is no doubt in my opinion that the variations have resulted from the circumstances I have referred to in my answers, to the five or six preceding questions, but in the case of the sample collected on November 8th, 1899, where the difference is said to be 90.9 per cent, there is no doubt in my opinion that the
9148 difference in that particular case is due to some arithmetical error, not including the result from the original data of the analyses, or a clerical error in putting down the figures in the record, or typographical error in preparing the plates for printing.

Q. Professor, referring to the total solids in suspension as determined by yourself, and Mr. Bisbee on that date, to wit, November 8, from the samples analyzed by you, what is the percentage of difference?

A. The difference between the suspended matters upon the date in question based upon Mr. Bisbee's figure, namely, 26 parts, as of 100 per cent., or 828 per cent. if based upon my own figures, 2.8 parts, as 100 per cent.,—amounts to about 90 per cent.

Q. What is the total residue in suspension in the two instances?

A. The total residue in suspension as given in any data is 2.8 parts.

Q. What is it in Mr. Bisbee's?

A. In Mr. Bisbee's 26.

Q. And what per cent. did you say?

A. Ninety per cent.

Q. Now the variations in nitrates based upon your fig-
9149 ures as 100 per cent, would be 48.8 per cent, would it
not, as between yours and Mr. Bisbee's on the same date, to wit, November 8th, 1899?

A. It would.

Q. And for the same date and same water, calculating yours as 100 per cent, the variations in free ammonia between yourself and those of Mr. Bisbee, would be 30.9 per cent, and of total albuminoid ammonia would be 28 per cent.

A. They are approximately 30.9 per cent and 28. per cent respectively.

Q. Expressed in percentage, professor, what are the limits of accuracy in your analyses of water for the different determinations of organic matter contained in those waters?

A It is my opinion that in all probability the limits of accuracy in my determinations of the organic matters in water are in general, about ten per cent.

Q. Now does that percentage apply in your determinations of the water in the Illinois river, the drainage canal and Lake Michigan, with reference to the total solids, oxygen consumed, chlorine, free ammonia, albuminoid ammonia, albuminoid ammonia dissolved and suspended; total organic nitrogen, and dissolved and suspended organic nitrogen, nitrites
9150 and nitrates?

A. It does not apply equally to all of these, but was stated by me in response to a question concerning the limits of accuracy in determining the proportions of organic matters.

Q. Professor, state the limits of variation as to accuracy in parts per million of all chemical constituents, or of each of the chemical constituents determined by you in your sanitary chemical analyses of the water of the Illinois river at Kampsville; that is to say, what are the limits of variations in the results of the various constituents as determined in your laboratory, and expressed in parts per million?

A. With respect to the limits of accuracy in the determination of total solids in my laboratory, I would say that the determination was ordinarily accurate within two or three per cent. That if we assume the true figure for the content of total solids to be 400 parts per million, the limit of accuracy in the determination as made in my laboratory would come easily within 395 parts per million on the one hand and 405 parts per million on the other, although I have made no special determination of this in the case in question, but base this opinion upon my general experience with the analyses of these and
9151 similar samples.

With respect to the determination of the proportions of dissolved matters there is at times in my opinion a wider variation than this, due to the difficulty of filtering out the suspended matters. With respect to the proportions of suspended matters the proportional variation will be at times even more considerable, dependent upon the degree of completeness with which suspended matter, which are in all cases determined as differences between the total and dissolved matters are removed from the sample in the process of filtration.

With respect to the determination of the loss on ignition, this is less accurate than the determinations to which I have just referred, and in fact today little significance is attached to this determination because of the inaccuracies involved and because it throws little light upon the nature or the amount of organic matter contained in the water, and has been by many chemists, engaged in the sanitary chemical analysis of waters altogether abandoned. The same statement applies to the loss on ignition of dissolved matters. The determination of chlorine as conducted in my laboratory is subject to a variation perhaps of a half of one part per million and in the case of waters containing little chlorine as chlorides this would make a high percentage difference between duplicate determinations if
9152 it were not for the fact that in such cases a greater quantity of water was used in the determination, and the experimental error between duplicate determinations which is practically a constant, was upon these greater quantities considerably reduced in proportion and percentage. That is, in waters which were low in chlorine a greater volume was used

in the determination, but being concentrated to the same volume, namely, 50 cubic centimeters, employed in all of the chlorine determinations, the constant experimental error was reduced in proportion to the quantity of chlorine contained in the original sample.

In the case of the oxygen consumed, duplicate determinations in my laboratory, probably do not in my opinion vary more than five to ten per cent. Stated in parts per million, if there were ten parts of oxygen consumed by the organic matters contained in a water sample, the variation in the determination might make the proportion recorded nine and one-half parts per million or ten and a half parts per million. This would apply proportionally to the oxygen consumed by dissolved and suspended matters, subject of course to the differences due to the difficulties of completely removing suspended matters from the sample as referred to above in my statements regarding determinations of dissolved and suspended solids, but not so great proportionally.

9153 The determination of free ammonia as conducted in my laboratory upon duplicate samples, is subject in my opinion so far as my memory now serves, for I have not expressive data here at the moment, to a variation of perhaps ten per cent, although it will vary in different cases, and the proportion of nitrogen as free ammonia determined in given cases, will be less or greater according as the distillation employed in removing the free or saline ammonia, from the rest of the constituents of the water in the process of determination, is pushed to a greater or less degree, for in the determination of the nitrogen as free ammonia, the albuminous matters, that is the various nitrogenous organic matters contained in the water, suffer a decomposition and yield some of that nitrogen in the form of free ammonia which distills over and is included in the determination of the nitrogen as free or saline ammonia.

On the other hand, there are losses in the condensation of the distillate in which the nitrogen of the free ammonia is to be determined, which losses may amount to as much as ten per cent or even more, but which on the average would not in my opinion, be so great as this. I may say that in the method of determination of the total organic nitrogen, free ammonia contained in the sample was distilled off under precisely the same conditions as those prevailing in the determination of the nitrogen as free or saline ammonia, and the attendant determination of albuminoid ammonia, and that the proportion of nitrogen as albuminoid ammonia thus separated preliminary to the determination of the total organic nitrogen was in all cases determined, and corresponded very closely with the proportion of nitrogen as free or saline ammonia determined in the portion of the sample used, especially for the determination of nitrogen as free or saline ammonia and nitrogen as albuminoid ammonia, thus giving a check upon the determination of total nitrogen contained in the form of free ammonia, and of organic nitrogen as determined by the process of Kjel Dahl. 9154

ADJOURNED until 2:00 P. M. same day, Monday, November 23rd, 1903.

2:00 P. M., Monday, November 23rd, 1903.

9155 Continuation pursuant to adjournment.

Present, the Commissioner and same counsel representing the respective parties.

PROF. ARTHUR W. PALMER,

resumed the stand for further cross-examination by Mr. Jeffries, and testified as follows:

Q. You may proceed with your answer to the last question professor, which was asked just before adjournment.

A. The variations in the determination of the proportions of nitrogen as albuminoid ammonia, as between duplicates run upon the same sample, would be probably as great as those upon the nitrogen as free ammonia, and to some extent would be the inverse of the same, that is, where the proportion of nitrogen as free ammonia in a duplicate was found to be greater the proportion of nitrogen as albuminoid ammonia in the corresponding duplicate would probably be smaller, but on the other hand the varying decompositions of the albuminous matters involved in the release of a portion of their nitrogen as free ammonia in the processes of analyses, would bring in other variations. On the whole, however, the determinations in my opinion do not

vary so greatly as those of the nitrogen as free ammonia.
9156 What has been stated in respect to the variations in the proportions of the dissolved and suspended matters in my statement concerning dissolved and suspended solids, and the oxygen consumed by dissolved and suspended matters, would apply to the determination of nitrogen as albuminoid ammonia from dissolved, and the nitrogen as albuminoid ammonia from suspended matters; since variations in the proportions of suspended matters removed by filtration would entail variations in the proportions of nitrogen as albuminoid ammonia derived from these substances in solution and in suspension, which vary as indicated in my statements above, according to the effectiveness of the process of filtration.

TOTAL ORGANIC NITROGEN.

The variations in the proportions of total organic nitrogen as determined by the Kjel Dahl process depend upon the completeness of the removal of the nitrogen as free ammonia, and the degree of decomposition of albuminous substances and other nitrogenous organic matters contained in the water in the process of removal of the free or saline ammonia. In the case of the waters analyzed by me in this series of investigations, the total organic nitrogen as determined, would from these causes probably be a little below the truth, for undoubtedly a small portion of the total organic nitrogen has been con-
9157 verted into the form of free ammonia in the process of distillation and removal of the nitrogen as free or saline ammonia, thus increasing the latter and being lost in the determination of the total organic nitrogen; but there are other sources of variation in the determination of the total organic nitrogen. The process involves the destruction of the nitrogenous organic matters through reaction with hot sulphuric acid, which destruction transforms the organic matters into inorganic substances, namely, carbon dioxide, water and ammonia. If in the digestion with the sulphuric acid the decomposition is not complete a portion of the total organic nitrogen may be left in such form that it does not appear in the subsequent processes as free ammonia, the form in which the nitrogen as total organic nitrogen is subsequently by the Nessler process,

quantitatively determined, thus giving a lower result. In my work upon this determination, care was taken to note so far as is possible, that the organic matters were completely destroyed, and to secure ourselves against the probability of any of the nitrogenous organic matters escaping, this complete destruction, and the complete conversion of the nitrogen contained in them, into the form of free ammonia, the liquids in the Kjel Dahl flask were heated for twenty minutes or half an hour
beyond the time which indicated the complete destruc-
9158 tion of the organic matters, that is, the complete clearing
up of the liquid and its becoming colorless, which ordinarily is regarded as showing the completion of said destruction. When the nitrogenous organic matters have thus been completely destroyed, which is attended by the conversion of the nitrogen contained in them into the form of ammonia, which remains in the form of a salt of ammonia in the sulphuric acid, in the flask. The next step in the process is the neutralization of the sulphuric acid by means of alkali and the addition of sufficient excess of alkali to set free the ammonia from the sulphate, the form in which it remains after the digestion of the sulphuric acid. At this point there is liability to error from loss of free ammonia, that is, the evolution and escape of free ammonia from the flask and later in the distillation there is liability to loss of free ammonia from imperfect condensation of the gas, as it is distilled off from the one flask in order to be condensed together with water as a distillate in another flask. Just how great the final loss and diminution in proportion of the total organic nitrogen from all these sources of variation is, I cannot state, but I am confidently of the opinion that as between any two duplicate determinations upon the same sample
as the determinations have been made in my laboratory,
9159 it is in my opinion not great, probably not beyond from
three to four per cent., and I very much doubt its amounting to as much as this.

The determination of the total organic nitrogen in dissolved and in suspended matters, the former of which is conducted in precisely the manner indicated above will vary from these same causes in the same proportion as does the determination of the total, but the distinction between the dissolved and the suspended matters depends not only upon these variations involved in the method itself, but also upon variations of the proportions of suspended matters removed from the original sample in the process of filtration as indicated in my statements with respect to the determination of other constituents, above.

Variations in the proportions of nitrogen as nitrites are far smaller in general than variations in the determination of the proportions of the other substances I have mentioned. It is true that the nitrites in particular vary from causes other than those mentioned above, often in far greater proportion than any of the variations I have referred to above, but from a given sample examined in duplicate in the laboratory the variations in the determinations between these duplicates will
9160 be extremely small. The sensitiveness in the process is frequently given as one part in 1,000 million, which would correspond to .001 parts per million as it appears in the analytical tables.

In the determination of the nitrogen as nitrates there is considerably greater variation owing to the fact that in the process employed, a portion of the nitrate may escape reduction to free ammonia, thus lowering the proportion found by Nesslerization of the free ammonia reduced in the process used and a further loss of the nitrogen undoubtedly takes place in the process of distillation of the free ammonia produced by reduction in this separation from the other matters present in the liquid, resulting from the reduction, and its conveyance into the distillate in which the free ammonia thus produced is to be determined.

Variations from these causes, as between duplicate determinations upon the same sample made in my laboratory, have amounted to from 2 to 20 per cent., and in general it is my opinion that the methods as conducted in my laboratory give results which in general are accurate to within about ten per cent., the results undoubtedly in all cases being below the truth, the variations from these causes not being such as to show more nitrogen as nitrates than was really present in the
9161 sample.

In considering the limits of accuracy in the determinations of these various substances, I would add that the proportions involved are stated in my testimony as parts per million, and that the quantities involved in all cases of determination of nitrogen in its various forms, are extremely minute. The determination of total organic nitrogen that has been referred to several times in my testimony today, one part per million corresponding to the determination of the presence of one pound of total organic nitrogen in a million pounds of water, and that of Mr. Bisbee referred to in connection with this involving as indicated by his figures, the determination of the quantity .6 of a pound of total organic nitrogen in a million pounds of water.

I would further add that in my opinion the comparison of the data of individual analyses from the various series of analyses introduced by me as evidence in my testimony does not constitute a very important part of said testimony, but that the comparison which I have instituted between the averages for the individual years, and for the three year period prior to January, 1900, and the three year period subsequent to the first of January, 1900, rests upon a reasonably accurate basis in fact, and that these averages made up as they are from the data of analyses of samples collected at regular stated periods, 9162 namely once a week, throughout the six year period mentioned, afford a sound basis for a comparison of the condition of the waters in the Illinois river at Kampsville during the two periods in question.

My opinion further is that the variations in the process of determination in the samples themselves, as they are collected, and which take place during the time that lapses between the actual moment of collection and the time the examination is begun, in the laboratory, are substantially the same for all the various samples taken throughout the entire six year period, and that consequently the data secured by the analyses of all these samples, that is, particularly the averages computed therefrom, are strictly and reasonably comparable for the purpose of showing the condition of the water at this point during the two periods.

It is true that the averages do not show all the variations in both directions which take place in the proportions of these

substances contained in the water, and as I have stated elsewhere in my testimony, they are neither intended to do this, nor can they be reasonably expected so to do any more than a table of the average mortality of men in a certain class of occupations, and of certain age, can be expected to show
9163 the variations in the length of life of said men, although it is made the basis for conduct of the business of life insurance, and I would further add that the variations which may take place during the period covered by the analyses and especially during the intervals of time between the collection of various successive individual samples are by no means so great as the variations in the length of the lives of men of a given class and occupation and age, which are included in the averages used by insurance companies as the basis for the insurance of the lives of men; for in cases where the average life of men of a given class and occupation and age may be 20 years, oftentimes it happens that individuals of this class decease within a few days or perhaps hours, and others live far beyond the average length of time alloted for the life of said individuals as computed by the actuaries of insurance companies in their tables of averages above referred to. On the other hand, there is in my opinion absolutely no probability that any such extreme variations or anything comparable with such extreme variations takes place in the proportions of the various organic substances contained in the waters of the Illinois river at Kampsville between the time of the collection of various successive samples.

With respect to the duplicate determinations of dissolved
9164 oxygen I would say that in general the variations between duplicates are but slight at times, reaching as much as one part per million out of from 15 to 16 parts per million as recorded in the results of the analyses, a variation of about six per cent., but take the entire series of examinations submitted by me in evidence, and it is my opinion that the variation between duplicate determinations for the entire series would fall far short of this, probably not more than .1 of a part per million on the average, although it is true I have prepared no averages from these series, that is, as between the duplicate determinations.

Q. Professor, is it not a fact that organic nitrogen results by the Kjel Dahl process are affected by high chlorine contents due to the formation and escape of tri-chloride of nitrogen?

A. As to that I cannot state definitely, for the reason that I know of no one who has demonstrated the presence of nitrogen tri-chloride in the mixture undergoing this reaction, nor in the products which escape during the action, but it is my opinion that high chlorides together with high nitrates, do result in loss of a portion of the nitrogen contained originally in the water in combination with organic substances.

Q. And may not that loss be a material percentage?

9165 A. I believe it may be.

Q. Professor, what allowances have you made for error in analyses made for organic matter due to changes enroute during the transportation of the samples from the place of collection to the laboratory?

A. I have made no allowances whatever for errors resulting from changes in the organic matters contained in the water samples while enroute between the point of collection and the laboratory, where the analyses were made, but have put in evidence the data precisely as they were obtained, as a result of the analyses in question, and am of the opinion that no allowances for this are necessary or important in this case, for the reason that the conditions as to the collection of samples, shipment and lapse of time between collection and arrival at laboratory and commencement of the analyses were similar throughout the entire six years period, and consequently such changes as may have occurred while the samples were being transported from the river point where they were collected, to the laboratory where they were analyzed, will have equally affected on the average those samples collected during the earlier three years period, and the samples collected during the latter three years period, and so do not militate against the reasonableness of the basis upon which my comparisons of the condition of the water during these two periods was

9166 made.

Q. Was there not a change in the organic matter contained in those samples while enroute from the point of collection to the laboratory?

A. There was undoubtedly some change in the organic matters contained in the samples of water while said samples were enroute from the point of collection to the laboratory, but these changes, as I have repeatedly stated, were undoubtedly similar in character and in amount on the average for those samples collected during the one period and the samples collected during the other period.

Q. How do you know that?

A. In my general experience in the examinations of waters for the purposes of determining their sanitary chemical condition I have made comparisons and comparative analyses of samples which have been kept for longer and shorter periods of time such as to demonstrate to my satisfaction the fact that organic matters in water samples which are allowed to stand for various lengths of time do suffer change in the nature of the proportional content of the organic matters in them, and in the case of the various data which I have introduced in evidence here I know that the conditions of temperature in the water samples, temperature of the air, length of time during which the samples were in transit, passed through the same
variations during the first three year period, that they
9167 did during the second three year period, that is, the first
three year period included the various seasons of the
year with all the seasonal changes as to flow of water in the stream, precipitation, temperature of air and water, variations in the content of the proportions of the different constituents of the water and so on, which were similar to the variations in all these respects which maintained during the second three year period. I have for my own satisfaction made some few determinations directed to the purpose of determining how much change took place during the time that elapsed between the collection of the sample and its arrival in the laboratory, with respect to the dissolved oxygen, this has been set forth in detail in my testimony heretofore given. Some determinations of nitrites in the waters of the Illinois river at Grafton on June 23rd and 24th, 1899, showed that in the water of the Illinois at Grafton on the morning of June 23rd, 1899, at a depth of one foot, there was about .025 parts of nitrogen as nitrites per million, and at a depth of 18 feet the same spot in the same waters

the proportion of nitrites was .028 parts per million, and about 30 hours later, that is, upon June 24th, at the depth of one foot, the proportion of nitrogen as nitrites was found to be .026 parts per million. Unfortunately, data for the nitrite determination upon samples collected at this
9168 time and transported to the laboratory, have been lost
or mislaid, but the data secured from the analyses of waters collected upon days just preceding and other days following, at intervals of one day, on the one hand and of four days on the other, in the time of collection of these samples, show the proportion of nitrogen as nitrites as contained in said samples to be .109 and .033 respectively, which are substantially comparable with the proportions of these constituents found in the samples taken upon the spot.

Upon July 21st, some determinations were made as the water was taken from the river at Averyville. I found the proportion of nitrogen as nitrites to be .25 parts per million in one sample, and .23 parts per million in another sample, while determinations at the laboratory made upon sample collected upon July 18th, showed .46 parts of nitrogen as nitrites per million, and determination upon the sample collected upon the 24th, examined in the laboratory upon the 25th, showed .29 parts of nitrogen as nitrites per million.

Determinations upon the water of the Mississippi river at Grafton made upon June 24th, 1899 practically at the same time, that is upon the same day as those referred to with respect to the Illinois at Grafton, showed a content of nitrogen as nitrites,
of .001 parts per million, while samples collected from
9169 the Mississippi river at Grafton upon the 21st and the
28th of June respectively and examined in the laboratory 48 hours after the time of collection, showed a content of nitrogen as nitrites .004 of a part per million and .002 of a part per million respectively.

Q. Professor, have you taken into account the errors if any, in each constituent analyzed by you from the samples of water during this period of years, due to sampling, that is, the samples of water analyzed not being the representative of all the water in the stream at the time and place of collection?

A. I have taken that into consideration in this respect, that in my opinion variations in the determinations due to variations in the sampling are eliminated in a long series of collections and analyses by the fact that at one time the variation will undobtedly be on the upward side, and at another, upon the downward side, so that in a long series of examinations of waters taken from the same river at the same point, these will neutralize each other, and thus afford a series of results which are strictly comparable in the form of averages.

Q. Then it is a fact professor, is it not, that the nitrogen compounds do change in transportation?

A. There is no doubt in my opinion but that such changes take place during transportation.

9170 Q. Professor, this morning you referred to the fact that certain methods might be used in making chemical determinations of water which would show a percentage of variation such as is shown by a comparison of the results obtained by yourself, with those obtained by Mr. Bisbee from samples of water collected from the same river at the same point by the same collector at the same time. Now I would like you to state in evidence what difference in methods would produce such great variations in results?

A. The differences which were the subject of several questions this morning, bore particularly upon the proportion of total organic nitrogen. In this determination the methods followed by Mr. Bisbee and by me were, in my opinion, in general, of the same sort, and the differences due to variations in the method rest upon differences in detail. So far as I am aware, it is my opinion that Mr. Bisbee gave less consideration to the possible loss of nitrogen contained in the nitrogenous organic matters, during the process of removal of the free or saline ammonia, and on the other hand, to the complete removal of the free or saline ammonia before adding the acid for the determination of the total organic nitrogen.

Then too, as was stated in his testimony, the heating with sulphuric acid was continued until the contents of the
9171 flask became colorless, or a faint straw yellow color. In
my own work, we were very careful, as I have stated above, in answer to questions of yours today, to distill off the free or saline ammonia from the portion which was to be used

for the determination of total organic nitrogen under precisely the same conditions as were maintained in the determination of the nitrogen as free ammonia to be so recorded in the analyses. That is, we collected this distillate and Nesslerized it as a duplicate determination of free or saline ammonia, and thus assured ourselves that such decomposition of the total organic nitrogen as may have occurred in this process was practically the same in the portion used for the determination of free or saline ammonia, and after it, of the nitrogen as albuminoid ammonia, and in that sample used for determination of the total organic nitrogen, and incidental to this, we thus assured ourselves of the fact that the free or saline ammonia was all removed from the portion which was subsequently to be treated by the Kjel Dahl process.

Then too, in the digestion with the sulphuric acid, we, as I have stated above, pushed the digestion beyond the point at which it appeared that the organic matters were all destroyed. That is, when from the appearance of the mixture in the flask we felt assured that the organic matters were act-
9172 ually destroyed, we continued the digestion for from twenty minutes to a half an hour, as a further assurance of complete destruction.

9173 Q. Now Professor, how do you reconcile your last answer with the statement made this forenoon that as to the constituent known as organic nitrogen the analyses determined by yourself, and those determined by Mr. Bisbee, upon comparison showed sometimes you found more of such a constituent and sometimes less than he did in his analyses?

A. The statements which I have made in my answer to your last question covered the variations in both directions.

Q. Professor, is it not a fact that animal matter is a more fruitful source of free ammonia than vegetable matter, other things being equal?

A. In my opinion it is.

Q. Professor, do you know anything about what is known as the septic process?

A. I do know a little.

Q. Is dissolved oxygen as shown by your analyses ever absent from the waters of the drainage canal or the Illinois river since the canal was opened?

A. I made but three or four determinations of dissolved oxygen in the waters of the sanitary canal, but such as I have made did not reveal the absence of dissolved oxygen therefrom, and I have at no time found the waters of the Illinois river in its lower stretches wholly devoid of dissolved oxygen.
9174 However, in the water of the sanitary canal at the Bear Trap Dam on August 14th, 1900, I found but 5.88 per cent saturation with dissolved oxygen and on June the 29th, at the same point, but 10.88 per cent saturation with dissolved oxygen.

Q. Is it possible for a septic operation to be going on in a water where analysis shows nitrogen in the form of nitrates?

A. With respect to that the only information which I have personally upon the subject is the result of examination of sewage entering, and the effluents proceeding from septic tanks which showed the presence at times of nitrates in the effluent of the septic tank, from which it may be inferred that a septic action going on within the tank, went on with the presence of nitrates.

Q. What were the conditions under which those analyses were made?

A. These were somewhat unusual conditions in that septic action was at the time defective, that is, not complete, the flow through the tank being greater than the capacity and condition of the tank really warranted, or in other words, there was too much work for the tank under the conditions.

9175 Q. Then it was more a settling tank than a septic tank wasn't it?

9175 A. In my opinion no septic action was going on evidently in the tank.

Q. How long did it take the sewage to flow through that tank?

A. As to that I could not at present give you the data.

Q. That tank was located at what place?

A. In the town of Urbana, Illinois, the tank belonging to and handling the sewage of Champaign, contiguous to the town of Urbana. Each town has a septic tank and has had for many years.

Q. Is it not a fact that decomposition and putrification reduce to their simplest and most noxious forms, the various compounds contained in sewage, and that they are restored to their natural conditions more rapidly in a septic tank than under any other conditions?

A. It is in my opinion true, that a septic tank affords one of the best and quickest means of resolving the constituents of sewage into simpler and less noxious forms, but the action of the septic tank never completely resolves these matters into the simplest forms, and following upon the series of decompositions which it produces, there must, in order to bring about the oxidation of these products and their conversion into other sets of simpler forms, be a new or other series
9176 of agencies set in operation.

Q. Professor, is it not a fact that during flood conditions in the Illinois river, that weekly samples may fail to reveal sediment of a very objectionable character?

A. Not in my opinion if the samples are collected during the said flood period.

ADJOURNED until Tuesday morning, at 10:00 A. M., November 24th, 1903.

9177 10:00 A. M., Tuesday, November 24th, 1903. Continuation pursuant to adjournment. Present, the Commissioner and same counsel representing the respective parties.

PROF. ARTHUR W. PALMER,

cross-examination resumed by Mr. Jeffries.

Q. Professor, how do you account for the variations reported by you in the total nitrogen discharged by Chicago sewage into the Illinois river, that is to say, 29.18 tons per day as an average for April, 1901, and 61.35 tons per day for October, 1901, when during 1900, the corresponding figures in your table show 38.74 tons for April and 27.44 tons for October?

A. This difference is very largely due to the fact that during the months of January, February, March and April, 1901, the pumps at Bridgeport, were not in operation, so that there was no discharge of sewage through the Illinois and Michigan canal, thus reducing particularly the quantities of nitrogen as free ammonia discharged in Chicago sewage into the Desplaines river. During the year 1900, on the other hand, the pumps were in operation continuously throughout the year.

8178 During the month of October, 1901 the pumps at Bridgeport were in operation, thus discharging nitrogenous organic matters and nitrogen as free ammonia through the Illinois and Michigan canal into the Desplaines river, in addition to the quantities sent down through the drainage canal. The abnormally high quantity of total nitrogen discharged through the two canals into the Desplaines in October, 1901, was due in the main to an unusually high content of nitrogen as free ammonia in the waters of the Illinois and Michigan canal during the month of October, 1901. Reference to the table of detailed analyses shows that for the four samples which were collected from the Illinois and Michigan canal at Lockport during the month of October, 1901, the following proportions of nitrogen as free ammonia, to-wit: 31.2, 35.2, 28.8 and 32.8 parts per million of nitrogen as free ammonia for the four collections upon the dates as follows: October 7th, 14th, 21st and 28th, respectively. Just what may have been the source of this high proportion of free ammonia in the waters of the Illinois and Michigan canal, I cannot say, but it is a known fact that the liquid raised by the Bridgeport pumps into the Illinois and Michigan canal comes mainly from the south fork of the south branch, which is practically a septic tank, and which
9179 receives the sewage and wastes of the stock yards district, and that in this liquid occupying the south fork of the south branch the content of nitrogenous wastes is subject to considerable variation.

Q. Is it not a fact professor, that the Bridgeport pumps in the Illinois and Michigan canal were in operation during the month of October in both years, that is, 1900 and 1901?

A. It is.

Q. Professor, if it should appear in evidence that a series of cross-section samples of water for chemical analyses give results materially different from the results of your analyses of samples collected at a single sampling station at a given time and place on the Illinois river, would not that affect the accuracy of your results according to the variation between your analytical data and those representative of the entire stream flow at the given time and place, assuming that the methods of analyses in all cases were substantially identical?

A. If the assumptions included in this question were all granted, the effect would not be to show that my analytical data were not correct, but they would show that the data of the analyses made by me for a single sample at the given point, was not fairly representative of the entire body of water
9180 passing down the stream past the cross-section line indicated by your question.

Q. Assuming that samples of water are collected for analyses from a river once a week, or 52 days out of 365 per year, is it not a fact that much deleterious organic matter may pass a given place in the river and escape detection by analyses?

A. That depends very much upon various conditions which are not stated in the question. It depends upon the place and upon the proximity of discharge of said deleterious substances. In the near proximity of the place where such substances are discharged into the river, it is a well known fact that oftentimes the mixing is not complete and that it is not completed for some distance below such point, so that a single analysis taken once a week at one point, at such a locality in a river might not reveal the presence of deleterious substances passing down at that point, owing to the fact of the incomplete mixing to which I have referred, but in cases where such mixing is known to be complete, then the analyses taken once a week at a number of points along the stream below that at which the mixing is complete will reveal the presence of such substances as are contained in the water, so far as the methods of sanitary chemical analysis subserve that purpose.

9181 Q. How do you account for the range of suspended residue on evaporation in 1900 in the Illinois river water at Averyville being from 1.6 to 297.6 parts per million, and in the same river water at Kampsville during the same year the range being from 4.8 to 1047.2 parts per million?

A. The suspended solids at Averyville as recorded in table 53, were 1.6 parts per million on February 6th, 1900, and 297

parts per million upon February 13th, 1900. Between these two dates there was a considerable rise in the Illinois river at various points along its course, due to rains and melting snow, one or both, and the conditions on February 6th at Averyville were those which obtained before this rise in the river, while the next date when samples were collected, namely, the 13th of February, the suspended matters were found to be 297 parts per million. This was just after this sudden rise of three feet as it appeared at Kampsville, but a more considerable rise in the upper part of the river. Naturally when rivers rise from rainfall, much surface wash is carried into the stream, thus adding to the proportions of suspended matters, and a further increased velocity of the stream at such times keeps in suspension other things being equal, a greater proportion of the suspended matters brought into the water and adds to such suspended matters by the erosion of the banks and sand-
9182 bars in the stream.

With respect to the data mentioned for Kampsville, a similar explanation affords the key to the occurrence, namely, the very considerable rise in the river at this point—two of them in fact between the dates of January 17th, 1900, when the figure 4.8 parts of suspended solids per million is given, and the figure 1047.2 parts suspended solids per million for February 14th. I may say too, that along the lower course of the Illinois river there are a number of minor tributaries which are subject to very sudden rise, and which at times bring down enormous proportions of silt and clay, so that the quantities of these matters contained in the waters of the Illinois, and the proportions of them contained in the waters of the lower Illinois are often far in excess of the proportions contained at many points further up the river, that is, towards its source.

Q. Professor, do your analyses show in any way whatever the effect of the sewage and sewage mud coming from Chicago down the Illinois river caused by the opening of the drainage canal, January 17th, 1900?

A. They do not, in my opinion.

Q. From your analyses I understand you to say then there is no evidence of any change so far as the effect of the sewage

and the mud coming from the City of Chicago and the
9183 Chicago river down the Illinois river immediately subsequent to the opening of the drainage canal in January,
1900?

JUDGE SPRINGER: The last question is a very different question. One says, "caused by the opening of the drainage canal, January 17th, 1900," and the other says "immediately subsequent to the opening of the drainage canal in January, 1900."

A. From my analyses there is nothing to distinguish between the various constituents determined by said analyses or such proportion thereof as was derived from the sewage of the City of Chicago and such portion as was washed into the stream in the sewage of other towns, and from the run-off along the tributaries and the banks of the Illinois itself during this period,—this applying to the analyses of the waters of the Illinois river itself. On the other hand there was and is shown in the tables of analyses and upon some of the plates,—one at least,—an effect in the Desplaines river at Joliet in a considerable increase in the proportions of nitrogen as free ammonia; of nitrogen as albuminoid ammonia; of total organic nitrogen as determined by the Kjel Dahl process during the time immediately subsequent to the opening of the Chicago main drainage channel upon January 17th, 1900, but in the
lower river, that is, along the Illinois river, proper, there
9184 is nothing in any analyses that does distinguish between
such matters as were brought at this time in from the sanitary canal or Chicago main drainage channel, and that brought in other ways into the waters of this stream as indicated above, in my answer. So far as the question assumes a great discharge of Chicago river mud at this time, I have serious doubts about such discharge ever having taken place.

Q. Professor, with your knowledge of the Illinois river prior to the opening of the present drainage canal and with your knowledge of both the Illinois river and the drainage canal since the opening of that canal, and assuming that the canal was opened, on the 17th day of January, 1900, and assuming further that immediately subsequent to the opening of that canal and during the latter part of January, the month of February and the early part of March, the water in the Illinois river at Grafton and the Mississippi river below Grafton, assumed a black sewage muddied condition at times, and that that condition pertained throughout the entire stretch of the Illinois river from the drainage canal to the intake tower at the chain of rocks at St. Louis, what if anything do your sanitary analytical examinations of the water of those rivers and of the canal show in reference to the presence of such polluting substance therein contained?

9185 JUDGE SPRINGER: I object to this question for the reason that it does not include in the assumptions contained in the question the assumption that such changes were not produced by the seasonal changes at that season of the year, or by a flood in the river which would have been sufficient to account for these conditions.

MR. JEFFRIES: So far as Judge Springer's objection is concerned, I will state to the Court that it makes no difference what the source of this polluting substance was. The question is based altogether upon the condition of the river at the time mentioned in the question, which was immediately subsequent to the opening of the Chicago Drainage Canal.

JUDGE SPRINGER: Still, the answer which counsel anticipates and desires to bring out, relates to the opening of the canal as the probable cause of the conditions to which he has referred.

MR. JEFFRIES: For the satisfaction of counsel I will state that the evidence thus far introduced as coming from the witnesses for the complainant and the witnesses for the defense is that such condition was caused by the opening of the drainage canal, but that proposition so far as this question is concerned, will not and cannot affect the answer of the witness.

JUDGE SPRINGER: I desire to say further as to what 9186 this record shows, is not for me to state at this time. The record will speak for itself.

MR. TODD: I object to the question for the reason that the assumptions contained in the question have not been proven, and that there is no evidence in this record for the complainant or the defendant that shows that a black sewage muddied condition obtained in the Illinois river at Grafton or the Mississippi river below Grafton during a period of three months as assumed in this question, and that no witness has testified to the presence of sewage from whatever source, as being in the river during these three months at that point, based upon vision, as I assume the question has reference to.

(Q. Question repeated.)

A. So far as the assumption of a black sewage muddied condition of the Illinois river water throughout its length, or at various points along it, and the same condition including Grafton and the Mississippi river between Grafton and the chain of rocks, is concerned, I would state as my opinion that such assumption is altogether beyond the fact, that no such condition was to my knowledge, observed along the course of the Illinois river, nor at Grafton, nor in the Mississippi river between Grafton and the chain of rocks, but that on the other hand, the results of my analyses, particularly those having to do with the appearance and the odor of the water, indi-
9187 cate that no such condition maintained or held except that in the upper stretch of the Desplaines river in the vicinity of Joliet, the odor of the water as recorded in table 44 of the series of analyses I have submitted, as gassy, from January 2nd to March 26th, 1900, and that the water in the Illinois river at Morris, collected upon January 26th, 1900, had an odor which is indicated as gassy. There is nothing else in the series of analyses included in my tables which indicates directly a more than usually large proportion of sewage contained in these waters. On the other hand the variations in color and in the proportions of suspended matters and in the color of the suspended matters contained in the water during this period, were not different from those observed in other years in like seasons.

I would further add that I obtained from the various collectors of water samples along the river, information concerning the appearance of the water at this time and in no case did they note an unusually dark or black sewage colored mud contained in the water. They failed to note anything particularly different from the usual appearance during the season of high water in the Illinois river, in the spring.

9188 Q. Is it not probable that during flood periods weekly analyses of river water taken at the same point may furnish much less accurate data than daily samples from the same river at the same place?

A. Under such conditions, that is, assuming a sudden flood, or a sudden fall during the intervals between collections of samples, such collection would not through the sanitary chemical analysis reveal all the conditions between these times; but several collections, a week apart, taken during a general flood period, will in my opinion, give fairly accurate evidence concerning the condition of the water during the intervals between. I may add that in order to cover such possible differences between the times of weekly collections, we made daily collections from the Illinois river at Grafton throughout most of the period now in question, namely the three months subsequent to the opening of the Chicago main drainage channel, and I have included in my answer above to the preceding question, the inspection of the records covering such daily collections and analyses.

Q. If such flood conditions happening upon your weekly samples should appear then in evidence, it would affect would it not, the accuracy of your average results?

9189 A. It would, as I have stated in my answer to the preceding question, for the other periods covered by such change in conditions of flow as take place between the date of collection of the yearly samples, but it would not affect the general averages for the year in such a manner as to make those for the different years incomparable with each other upon a substantially accurate basis, for the reason that the same variations appear in the flood seasons of different years.

Q. Assuming that on an average deleterious organic matter coming from Chicago sewage and entering the Illinois river, would become innocuous by the time it reaches Averyville, and assuming further that on certain occasions such deleterious organic matter reaches the chain of rocks at St. Louis before it becomes innocuous, would the statement of averages, the average conditions alone, be true and correct when the matter is viewed from a sanitary standpoint, as a practical proposition?

MR. TODD: I object to the question because the assumptions contained in the question have not been proven, and for the further reason that the time between Chicago and St. Louis

as put in the evidence is in excess of a week, and that
9190 the innocuous matter cannot pass from Chicago to the
chain of rocks without being present at some of the points where samples of water were taken from which the analyses were made, for the making of the table of averages.

A. I am not ready to grant the correctness of the second assumption, but the truth and correctness of the tables of averages are independent of any standpoint, whether that of a sanitarian or a chemist of a mathematician, and in my opinion they afford a proper and reasonable basis for the comparisons which I have instituted between the averages for the various years and for the two three year periods.

Q. If the sanitary chemical analysis of the water shows the water in question to be good during 51 weeks in the year and unsafe for drinking purposes for one week, would the average results for the year reveal this feature?

JUDGE SPRINGER: I object to this question because the assumption has not been proven in this case. It is a mere abstraction, and any answer to it cannot be responsive to any of the issues involved in this case.

A. If we should grant the first assumption and the second assumption, the average results for the year could not be expected and would not be intended to show the condition assumed in the second assumption.

9191 Q. Wouldn't it be possible to have several analyses of
the water in question which would be called unsafe for drinking purposes and still not have the facts disclosed by the analyses of such samples covered by the results, as stated in your table of averages, or in the tables of averages?

A. That might very easily be the case, but I wish here to call attention to the fact that all the various analyses are given in the tables together with the averages; that is, at the foot of each table covering a year or a lesser period, in case the whole year was not covered by the analyses and analyzed, the averages appear for such periods.

Q. Professor, assuming that there is discharged into the Illinois river by means of the drainage canal, the sewage from the city of Chicago which contains certain organisms which produce typhoid fever; assuming that those organisms are of

a living character and that they live in the sewage of Chicago the drainage canal and the waters of the Illinois river from five to thirty days or more, disappearing by death gradually at from five to thirty days or more until at the end of thirty days or more, all have become innocuous; assuming further that they flow down the canal to the Illinois river with the water and with the same velocity as the water in the canal and
9192 the river. Assume that the mean velocity from Chicago to St. Louis is eighteen days; assume that the average life of these organisms has expired at some point between Averyville and Grafton, but assume also that as heretofore stated, the extreme life limits will carry them in thirty days or more to a point far below St. Louis. State whether or not a table of averages upon the life limit of these organisms, which shows that such average took place at some point in the river between Averyville and Grafton, can be used by a sanitarian, or by a sanitary chemist, as proof from a practical sanitary standpoint that no such disease producing organisms pass a given point between Averyville and Grafton and do not reach the St. Louis intake at the chain of rocks and pass beyond the city of St. Louis.

JUDGE SPRINGER: I object to this question for the reason that it assumes the existence of a table of averages as to the longevity of pathogenic micro-organisms, which fixes that longevity at from five to thirty days. As no such table of averages has been introduced in this case, any answer which the witness could give as to the effect of such table would not tend to prove any of the issues in this case, and for the further reason that the testimony already submitted in this case by Professor Zeit, based upon actual experiments as to the
9193 longevity of the typhoid fever bacteria, in the water of the Illinois river at Grafton, places the limit of the longevity of said micro-organisms at six days.

MR. JEFFRIES: I suggest to the Court that the testimony of Professor Zeit, does not show any such conditions or any such fact, and I suggest also that it is not a question of what the testimony of any one witness of the defense shows, but of what the testimony of all the witnesses as to the longevity of the typhoid bacilli or any other disease producing germ is in water, such as the drainage canal and the Illinois and the Mississippi rivers.

I suggest to the Court further in answer to Judge Springer's objection, that this witness has stated that the science of chemistry did not disclose the kind, character or characteristics of disease producing organisms in water. That the witness did state that if such disease producing organisms were in water that they would be and appear in the total organic nitrogen, the evidence in this case shows that the organic nitrogen commences in the canal and continues to Grafton in the Illinois river and to St. Louis. I suggest also that the witness is unable to
state that anything in the science of chemistry would dis-
9194 close the fact whether or not disease producing or-
ganisms will disappear in canal water as rapidly as other nitrogenous organic matter, and I suggest the witness has so testified and has made tables of averages and exhibited them in evidence upon the subject of total nitrogenous matters contained in the waters of the Illinois river and as this evidence in this case shows that the longevity of the typhoid bacilli is from five to thirty days or more, varying according to the testimony of the various witnesses, that the question is competent for the purpose of showing that no reliance can be placed upon such table of averages as applied to the science of chemistry, and as applied to the sanitary chemical analysis of water in a running strem.

JUDGE SPRINGER: I desire to suggest to the Court in response to the statements submitted by Mr. Jeffries, that a designation of pathogenic micro-organisms as other nitrogenous matter is not correct as applicable to the nitrogenous organic matter disclosed by chemical analyses. That the presence of pathogenic micro-organisms in water depends solely upon the fact as to whether there has been a human being having the disease of typhoid fever, or a disease produced by other pathogenic germs, and whether the dejecta of such patients has been
deposited in the water, and that whether these chemical
9195 tables disclose the nitrogenous organic matter or not,
does not tend to prove in any way the presence or absence of pathogenic micro-organisms, and that the question in this respect is misleading and improper.

A. It, in my opinion cannot, but the conditions prevailing in the Mississippi river between Grafton and the chain of rocks as to the mixing of the waters in the Illinois with the waters of the Mississippi and the waters of the Missouri, render it, in my opinion, highly improbable that any considerable proportion of such pathogenic germs as may be contained in the waters of the Illinois at Grafton,—that is, if we grant the assumptions of the question passes down the Mississippi to the point below, St. Louis, and is taken into the intake of the St. Louis waterworks.

ADJOURNED until 2:00 P. M. same day, Nov. 24, 1903.

2:20 Tuesday, November 24th, 1903.

9196 Continuation pursuant to adjournment.

Present, the Commissioner and same counsel representing the respective parties.

PROF. ARTHUR W. PALMER,

resumed the stand for re-direct-examination by Judge Springer and testified as follows:

Q. Professor, is there in your opinion, any evidence given by your analyses that septic action takes place in the waters of the drainage canal?

A. In my opinion there is.

Q. Will you give your reasons for that opinion?

A. The comparisons of the averages which appear in table D heretofore introduced in my testimony representing the analyses of the waters taken from the sanitary canal at Kedzie Avenue at its Chicago end, and taken at Lockport at the Bear Trap dam, for the four summer months, June, July, August and September, 1900, show a series of changes of the organic matters which are of the same nature as the changes which take place during the passage of sewage through a septic tank.

9197 MR. JEFFRIES: I move to strike out the question and the answer and any further answer that the witness may give to this question for the reason that it is not proper re-direct examination.

JUDGE SPRINGER: I will state in regard to this fact, that the subject of septic action was referrred to, only incidentally, in the direct examination of this witness, but was brought out by cross-examination.

MR. JEFFRIES: Not with reference to the canal nor the Illinois river.

JUDGE SPRINGER: What reference would it have then?

MR. JEFFRIES: The only question was, I asked the witness whether he knew what septic action was, and asked him to explain it, and that was withdrawn, and the only reference made to septic action was that made with reference to a septic tank or tub at Urbana, Illinois, as stated by the witness, and that the cross-examination extended no further than that.

JUDGE SPRINGER: I desire to state in reference to this objection that whatever reference witness made to septic action in the tanks at Urbana, Illinois, had some bearing I assume, upon similar action in the Chicago drainage canal; othewise it would have been incompetent and would not have borne
9198 upon any of the issues in this case.

MR. JEFFRIES: I would like counsel to state whether or not that inference, applied, if it was an inference, to conditions prior to the opening of the drainage canal or subsequent to the opening of the canal. I have never cross-examined the witness on the septic action of the water in the Chicago river prior to the opening of the canal, nor in the canal since the opening, nor in the Illinois river. The question that I asked was a general question with reference to the witness' knowledge upon the question of septic operation, and if it was true that the witness was qualified to speak of the septic conditions of the Illinois river, and of the canal since the opening of the canal it was competent and proper for defendant to have examined the witness in reference thereto, in chief and not have delayed the matter until his re-direct examination. I submit that such manner of examination of the witness is unfair for the reason that it eliminates a large part of the knowledge and information of this witness if he is acquainted with the septic operation of the water in the Illinois river and the drainage canal and the canal prior to the opening, until after the cross-examination has been completed, and for this reason is contrary to all rules

of evidence bearing upon the direct examination, cross-
9199 examination, re-direct and re-cross-examination of witnesses.

JUDGE SPRINGER: If counsel for complainant insists that the reference made in the cross-examination, made to the septic action taking place in the tanks at Urbana, had no bearing upon this case, then I withdraw the question.

MR. JEFFRIES: I will state now that the only object and the only purpose that I had in asking the question of this witness as to whether or not he was acquainted with the septic operation of sewage in a septic tank, was for the purpose of either showing that the witness did or did not know, in order to give the Court an opportunity to determine the credibility of the testimony of this witness, as a whole, and to determine the weight of the testimony coming from the defendants, who placed the witness on the stand and on the examination made in chief.

JUDGE SPRINGER: Then it was for the purpose of affecting the credibility of the witness and not for the purpose of proving the fact?

MR. JEFFRIES: For the purpose of proving the credibility of the witness' testimony and also for the purpose of showing the strength and weight to be given the testi-
9200 mony because of the defense having withheld such examination until after he had been cross-examined.

JUDGE SPRINGER: It seems therefore that the introduction of the subject on cross-examination was for a double purpose, not only to bring the fact into the case, but of testing the witness' credibility, and for this reason, it is competent for the witness to explain fully his opinion upon this subject.

MR. TODD: I desire to suggest that as far as a violation of the rules of proper examination of witnesses is concerned, that that rule has been violated from the very beginning of this case and any question that was asked was objected to and the answer given and recorded in the record, and if the facts appear that counsel interrogated the witness on the question of septic action, the fact that counsel states the limitations he placed upon the object of his cross-examination is not patent from the record, but merely from counsel's statement, and in

view of the statement that the examination went not only to the weight of the testimony, but to the credibility of the witness, and in view of the fact that counsel is not precluded from further cross-examination even if it appears to be new matter to the Court, we deem the question of sufficient importance, in view of all the circumstances, to be competent at this
9201 time, reserving to the complainant all rights which he may see fit to avail himself of. •

(Question and answer read).

THE WITNESS: (Continuing) Thus the average proportion of the total oxygen consumed by the water collected from the sanitary canal at Kedzie Avenue, was, for the four months in question, namely, June, July, August and September, 1900 8.9 parts per million, while the proportion contained in the waters collected at the Bear Trap Dam during the same period was upon the average, 8.8 parts per million, showing a reduction of 1.1 per cent in the proportions of total oxygen consumed. The proportions of oxygen consumed by the dissolved substances in the water at Kedzie Avenue, were 4.6 parts per million, while the proportion required by the water at the Bear Trap Dam was 7 parts per million, showing an increase in the proportion of oxygen consumed by dissolved matters as between the samples collected at these two points on the drainage canal, of 52 per cent.

The proportion of oxygen required for suspended matters was, for the samples collected at Kedzie Avenue 4.3 parts per million, while the proportion required by the waters collected at the Bear Trap dam were 1.8 parts per million, showing a reduction of 6 per cent.

The average proportions of free ammonia found in the waters at Kedzie Avenue, were 1.174 parts per million,
9202 while the proportion found at the Bear Trap dam was 1.235 parts per million, showing an increase in the proportion of nitrogen as free ammonia of 5.2 per cent.

The nitrogen as albuminoid ammonia, that is the total for Kedzie Avenue, was .45 parts per million, while the proportion found at the Bear Trap dam was .426 parts per million, a reduction of 5.3 per cent.

The proportion of nitrogen as albuminoid ammonia derived from dissolved substances was for the Kedzie Avenue sample, .158 parts per million, and for the sample collected at the Bear Trap dam it was .218—showing an increase between these two points in the dissolved albuminous matters in the proportion as against the nitrogen contained, of 38 per cent.

The nitrogen as albuminoid ammonia derived from suspended matters was, in the Kedzie Avenue sample, .292 and for the samples at the Bear Trap dam, .208—showing a reduction between these two points of 28.7 per cent.

The total organic nitrogen for the Kedzie Avenue samples was 1.047, and for the samples taken at the Bear Trap dam, it was .902, a reduction of 12.9 per cent.

The total organic nitrogen derived from dissolved matters was at Kedzie Avenue, .365, and at the Bear Trap dam .435, an increase of 19 per cent.

9203 The total organic nitrogen in suspended matters was, for the samples taken at Kedzie Avenue, .682 parts per million, while the proportions found in the samples collected at the Bear Trap dam were .467 parts per million, showing a reduction of 31.5 per cent.

These changes, which occurred during the time of the passage of the water from the upper opening of, or the entrance to the Chicago main drainage channel, and the out-flow of these waters at the Bear Trap dam are similar to the changes that occur during the passage of sewage through a septic tank in this particular, that the proportion of free ammonia is increased, and that nitrogenous organic matters and other organic matters which were in suspension, have been taken into solution and thus brought into a condition which prepares it for the next process of purification, namely the oxidation which occurs as these waters mix with the waters of the Desplaines and the Illinois, and flow on down the course of the Illinois river; that is particularly the oxidation of the organic matters and the nitrification of the same; these two sets of processes resulting in the destruction of much of the organic matter, part of it being converted into gases, the oxidation process producing mainly carbon di-oxide and water, and from the nitrogen producing nitrites and nitrates.

9204 Q. Professor, to what do you ascribe the fact mentioned in your testimony, that no unusual appearance of black sewage muddiness occurred in the waters of the Illinois river, just after the opening of the main drainage channel upon January 17th, 1900, and that the data of your chemical analyses show no unusual conditions of these waters for the season in question?

MR. JEFFRIES: I suggest that the witness made a complete explanation in answer to the question upon that subject on cross-examination.

JUDGE SPRINGER: I asked him to what he attributes this fact.

MR. JEFFRIES: The fact that it does not show or that it does show?

JUDGE SPRINGER: That it does not.

Q. (Question repeated).

A. In general I ascribe this to two conditions or circumstances. In the first place the waters or the sewage began to flow from the Chicago river into the drainage channel in the early morning of the second day of January, 1900, and slowly passed into the same during the following twelve days, so that the drainage channel was filled with such discharges including water drawn through the river from the lake by the 14th 9205 of January, and that during this period of slow dilution and standing in the drainage canal and the subsequent period of three days during which it stood quiescent in the canal, septic action took place which would tend to destroy much of the organic matters contained therein, and prepared it for the more speedy destruction after it had mixed with the natural waters of the Desplaines and the Illinois, the amount of dilution, taking the whole cubic contents of the Chicago river as the basis of comparison and the cubic contents of the sanitary canal, showing that the dilution during the filling of the sanitary canal amounted to 7.84. That is to say, the water of the Chicago river, which was introduced in the canal amounted to one part as against 6.84 parts of lake water drawn through the Chicago river while the contents of the Chicago river were being drawn into the drainage canal.

The other general condition I referred to previously in my

testimony. It is that just at the time and immediately following the opening of the gates at the Bear Trap dam at Lockport which permitted the first discharge from the sanitary canal into the Desplaines and thence into the Illinois river, namely, upon January 17th, 1900 there was rain, and the stages
9206 of water in the Illinois river throughout its course were
increased, that is, the waters were raised from the volume brought into the stream from its natural watershed, tributaries and its own banks. The rise at Averyville at this time, as between the 17th of January, 1900, and the following days, amounting to .6 of a foot; that is from the stage of 5.1 feet upon the 17th of January, the water rose to the stage of 5.7 upon the 18th; to 6.1 upon the 19th; to 6.6 upon the 20th; to 7.1 upon the 21st; to 7.5 upon the 22nd; to 7.7 upon the 24th; 8.15 upon the 25th; same height for the next two following days, that is the 26th and 27th; it fell to 7.9 feet upon the 28th, a rise of three feet at this point between the 17th day of January and the 25th.

Q. Professor, you have been asked several questions on cross-examination in reference to the limits of accuracy in the determination of the various substances disclosed by your analyses of the waters in question. Taking into consideration all such limits of accuracy and all other data which you have collected in this investigation, and all the environments of the situation, what is your opinion as to whether the condition of the waters of the Illinois river at Kampsville, samples of which you have analyzed and about which you have testified in this case, is substantially shown in your sanitary chemical
9207 analyses of the waters of the Illinois river at that point
for the periods in question and whether these examinations do or do not show substantially the sanitary chemical condition of all the water which passed over the Kampsville dam during the entire six year period from 1897 to 1902, about which you have testified in this case?

MR. JEFFRIES: I object to the question, first because it is not proper re-direct examination; second, for the reason that it shows the inaccuracies and variations in his analyses, with his general information and the purport of the question is directed to the examination of the witness on cross-examination with reference to the inaccuracies in the sanitary chemical analysis of the water; and for the further reason that it is simply an effort on the part of counsel to duplicate in the form of an opinion a conclusion which the witness has already stated in his direct-examination.

JUDGE SPRINGER: In my opinion it is competent cross-examination for the reason that there was no reference made in the examination in chief to these assumed inaccuracies to which the cross-examination was so much directed.

MR. JEFFRIES: I object to the statement of counsel, that the inaccuracies so assumed by counsel—the inaccuracies are an admitted fact as coming from the witness.

9208 Q. (Question repeated).

A. It is my opinion that the data of the analyses which I have read in evidence, and to which I have testified in this case substantially represent the sanitary chemical condition of the waters in the Illinois river at Kampsville during the entire periods covered by the series of examinations, and that in particular the comparison of the averages for the various years and for the two three year periods rest upon a substantial and sound basis.

RE-CROSS-EXAMINATION,

By Mr. Jeffries.

Q. Professor, in any year under consideration, what approximately is the total volume of water in cubic feet, that you have analyzed, with reference now to the Illinois river and the drainage canal?

A. Between 700 and 800 samples—call it 750 though.

Q. How many cubic feet would that be?

A. It would be 100 cubic feet of water.

Q. Now then, what per cent is that of the total flow down the Illinois river, or through the main drainage canal at Lockport in any one examination?

A. The discharge of the sanitary canal at the Bear Trap
9209 dam was, during that year, 188,000 cubic feet per minute.

Q. How much would that be per hour?

A. Sixty times that during the hour.

Q. And that would amount to how much?

A. 270,720,000 cubic feet per 24 hours, if my arithmetic is correct.

Q. And per annum?

A. 98,812,800,000 cubic feet per annum.

Q. Now what per cent of that is the total amount in cubic feet that you analyzed, which was as stated by you, 100?

A. It was 1,198,812,800,000th part of that quantity of water.

Q. Now professor, in your opinion, is there septic operation in the waters of Lake Michigan 100 feet out in the lake at the mouth of the Chicago river, or which was formerly the mouth but which now is the head waters of the Chicago river?

A. I have no direct evidence upon that point, but in my opinion, there have been times in the past when septic action took place in and near the mouth of the Chicago river.

9210 Q. Has there been since the opening of the Chicago drainage canal?

A. I do not know.

Q. What is your opinion?

A. I have not considered the matter at any time.

Q. Then you have no opinion upon that proposition?

A. No.

Q. And as a chemist, having made thousands of sanitary chemical analyses of water from the Illinois river, the main drainage canal and Lake Michigan, you have no opinion upon the proposition as to whether or not there is, since the opening of the canal, septic operation in Lake Michigan 100 feet out in the lake, from the former mouth and now source of the Chicago river?

JUDGE SPRINGER: I submit that the answer to this involves merely a question of fact and not one of opinion, and if witness has obtained no data by analyses of the waters at that point, he is unable of course to answer as to the fact as to whether there is septic action at that point.

MR. JEFFRIES: If the witness does not care to give an opinion he need not do so.

A. In the absence of direct knowledge of the conditions prevailing in the bottom, near and in the mouth of the
9211 Chicago river, I can make no definite statement in answer to this question, but in a general way would state it is my

opinion, that in all probability, at times there is still septic action going on in the sediments in the bottom of the lake in the vicinity of the mouth of the Chicago river.

Q. Then professor, the water that is discharged from Lake Michigan into the canal and thence into the Illinois river, is not at all times the same so far as its chemical constituents are concerned, is it?

A. Not precisely the same. That fact is shown in the tables of analyses which we have put in evidence, which show that the water four miles out is not at all times of precisely the same composition.

Q. Then professor, if you are correct in your opinion that since the opening of the drainage canal there is at times septic operation in the waters of Lake Michigan, 100 feet from the former mouth and now 100 feet from the source of the Chicago river, the water that flows through the Chicago river into the canal and thence into the canal from Lake Michigan is at times polluted, is it not?

A. Not at all. That does not follow from my statement, which was to the effect that lacking evidence, never-
9212 the less I am of the opinion that at times septic action is taking place in the sediments in the bottom of the lake in the vicinity of the mouth of the Chicago river.

Q. If septic operation is taking place in the sediment, would not that operation to some extent be affected by the sediment in the water itself, and from the contents of the water?

A. That is quite possible and probable, even down so far as the drainage channel.

Q. And is it not true that if septic operation is taking place in Lake Michigan at the mouth of the Chicago river, even in the sediment or in the water itself, that it indicates certain quantities of organic matter in course of putrification and decomposition?

A. It certainly does the latter, and everybody who has investigated the matter knows that certain sewers of Chicago still discharge into the lake, and that refuse matter from various places has been at times dumped along the margin of the lake, which afford the basis for the opinion I have given, although lacking chemical analyses in evidence, that septic action does at times take place in the sediments of the lake in the vicinity of the mouth of the Chicago river,--the former mouth of the Chicago river.

9213 Q. Professor, in your compilation of the total amount of the various chemical constituents passing through the main drainage canal at Lockport, you stated, and it is shown in the tables that were read in evidence by you, that there was .2 per cent of those constituents which were due to such constituents contained in the Lake Michigan water that passed through the canal and was mingled and mixed with the sewage of Chicago, did you not?

A. I did.

Q. Did you obtain those percentages from any analyses made of the chemical character of the water in the lake as it passes from the lake into the drainage canal or into the Chicago river?

A. No; those proportions were based upon my analyses of water drawn in at the Four Mile crib, opposite 14th Street.

Q. In your opinion is it a fact or not that there are more of those organic substances contained in the water at the mouth of the Chicago river, as it now is, at its junction with Lake Michigan, than there was in the water analyzed by you which was drawn from the Four Mile Crib?

A. In all probability at times there is a slightly greater proportion of these substances contained in the water as it enters the old mouth of the Chicago river than is contained in the waters of the city supply drawn at the intake crib opposite 14th Street, but such matters have 9214 directly or indirectly been derived from Chicago sewage, and consequently the difference between those quantities contained in the lake water further out, and the quantities found in the waters of the Illinois and Michigan canal, and the waters of the sanitary canal show the sum total of nitrogenous organic matters and nitrogen as free ammonia derived from Chicago sewage.

Q. So then, so far as your data is concerned, it makes no difference and you have taken into consideration also the fact that the sewage from Chicago is discharged into the drainage canal not only by reason of the sewers themselves discharging into the Chicago river, but because they also discharge into Lake Michigan and thence through the mouth of the Chicago river into the canal; isn't that true?

A. I have given very little weight to the latter point, because of its significance as compared with the proportions of Chicago sewage which are directly drawn into the Chicago river and thence into the two canals, which discharge it into the Desplaines.

Q. It is your opinion then that the difference between the condition, chemically speaking, of the water at the Four Mile Crib and the condition of the water at the mouth of the 9215 Chicago river, is of no consequence so far as the percentage of the total amount of tonnage of organic matter that passes over the Bear Trap dam is concerned?

A. Not exactly that. I mean to say that nothwithstanding that difference at the dam which so far as I am aware, has not been specifically determined, that in spite of such differences, the data I have given regarding the quantities and the proportions of these nitrogenous organic matters and nitrogen as free ammonia discharged through the two canals, including that discharged by the Bear Trap dam and that discharged at Lockport and Joliet through the Illinois and Michigan canal represent with substantial accuracy the quantities of these matters introduced into the Chicago river and the two canals and discharged thence into the Desplaines, in Chicago sewage.

Q. Professor, in your opinion, is septic operation going on in Lake Michigan at the point in the lake where are located any one or all of the four intake cribs which furnish the water supply of the City of Chicago?

A. In my opinion it is not.

Q. Then is it not a fact, professor, that the water that passes from Lake Michigan into the drainage canal and down the Illinois river, is more polluted as it comes from Lake Michigan than the water that is drawn by the City Water depart- 9216 ment, from the various cribs located in Lake Michigan opposite Chicago?

A. I have no doubt—in my opinion the water which enters the old mouth of the Chicago river, is inferior in quality in the respects indicated in the question, to the waters drawn into the city supply through the intakes at the various cribs, but it is my opinion further that the difference is not at all to be compared with the difference between the city water which enters the old mouth of the Chicago river and the water which passes out of the Chicago river into the drainage canal, or is pumped out into the Illinois and Michigan canal.

Q. Is it not a fact in your opinion that the water that passes from Lake Michigan into the Chicago river and thence into the canal that as it passes from the lake into the canal it is in an unsanitary condition?

A. It becomes undoubtedly in my opinion of an unsanitary condition as it passes through the Chicago river into the sanitary canal, because of the introduction of Chicago sewage on the way.

Q. Isn't it in an unsanitary condition before it leaves Lake Michigan and passes into the river?

A. I have no doubt that at times it is.

9217 Q. What in your opinion would be the effect upon the people of Chicago if they should obtain their supply of water at the old mouth, now the source of the Chicago river, that supply being obtained 50 to 100 feet in Lake Michigan away from the mouth of the river?

A. In my opinion at times the water if drawn into the city supply system at this point, would be in an unsanitary condition.

Q. Professor, when you stated the average amount of oxygen consumed in the water of the drainage canal in June, July, August and September, 1900, was 8.9 parts at Kedzie Avenue, and 8.8 parts at Lockport, how are you able to state that it shows a reduction of one per cent, when you admit the difference is within the limit of accuracy of your analytical determination?

A. For the reason that these are averages based upon a number of analyses and as I have repeatedly stated in my testimony, the differences being in both directions, the averages eliminate most of the errors of the averages for two sets of analyses made under the same conditions, and are consequently comparable for purposes of representing and showing the differences in proportional content of the various substances. However, that particular difference is not one of any great moment. 9218

Q. In other words, it is not a measurable or an appreciable difference?

A. One per cent is sometimes appreciable. In this case it is of no particular significance.

Q. Then sometimes a difference of one per cent in the limit of accuracy is appreciable, is it not?

A. Sometimes; it depends on what it is. One per cent in the determination of the content of gold in ore, is of more significance than in a case of this sort.

Q. But so far as this case is concerned, it is inappreciable?

A. I say in this particular case the total oxygen consumed referred to in my statements regarding the waters of the drainage channel at Kedize Avenue and at the Bear Trap dam—

Q. Is what? Inappreciable?

A. Insignificant. Or rather I said, not particularly significant.

Q. Then the oxygen consumed represents the carbonaceous matter?

A. To a certain extent it does.

Q. Then there is no appreciable reduction as the water flows through the drainage canal?

9219 A. So far as that determination shows, there is no appreciable reduction in the total oxygen consumed.

Q. Professor, do you not know that the degree of dilution of Chicago sewage by Lake Michigan water in the drainage canal, which degree was investigated at great length by the Hering Commission in 1886 and 1887, and upon which the legislative Act creating the Sanitary District of Chicago was predicated, and upon which the present canal in question was predicated, was for the special purpose of preventing septic action in the main canal and that it was absolutely absurd to denominate the chemical changes in the drainage canal as those of a septic process, as that proces is regarded by sanitary engineers?

JUDGE SPRINGER: I object to the assumption in regard to the reason for the passage of the Act establishing the Sanitary Canal as not being accurately stated.

A. I do not know precisely that the degree of dilution called for by the determinations of the Hering Commission was intended to entirely prevent septic action, but I am of the opinion that those changes in the nitrogenous organic matters contained in the waters of the sanitary canal to which I have testified are of the character of the changes which are produced in such matters in the changes of sewage while passing through septic tanks.

ADJOURNED until 10:00 A. M. Wednesday, Nov. 25, 1903.

9220 (Very shortly after Prof. Arthur W. Palmer completed giving his testimony, he was taken ill and never recovered. His much to be lamented death occurred on the 31st day of January, 1904. He had corrected his testimony up to the beginning of his cross examination. From that point down, such typographical corrections have been made, as were necessary to give the sense of what witness said.

FRANK S. BRIGHT,
Commissioner.)

9221 10:00 a. m., Wednesday, November 25th, 1903. Continuation pursuant to adjournment.

Present, the Commissioner and same counsel representing the respective parties.

THOMAS J. BURRILL,

called as a witness in behalf of the defendants, being first duly sworn by the Commissioner, was examined in chief, by Judge Springer, and testified as follows:

Q. You may state your name, residence and occupation?

A. Thomas J. Burrill; Urbana, Illinois; a member of the faculty of the University of Illinois. I hold now the professorship of botany.

Q. Where were you educated, Professor?

A. Illinois State Normal University.

Q. What courses did you pursue there?

A. It was a course largely for teachers, and I specialized as much as possible in science.

Q. What branches of science?

A. Biology.

Q. When did you quit that institution?

A. 1863.

9222 Q. Have you made any special studies in reference to biology since that time?

A. Yes.

Q. Where, and what were they?

A. Continuously since that time, in the larger field of botany, but more especially cryptogamic botany, and more especially still the group of fungi in which we class the bacteria.

Q. Where were those studies pursued?

A. I took up the subject by myself, as I was forced to do at that day; and at my home in Urbana largely, and elsewhere in the country as I could find opportunity.

Q. Have you attended any other university as a student?

A. Not as a regular student.

Q. How long have you been engaged in teaching at the University of Illinois?

A. Thirty-five years.

Q. Did you teach in any other school or university prior to that time?

A. As an assistant for one year, in the State Normal University. Afterward as principal of a public school—city school.

Q. What branches have you taught in the University of Illinois during the time you have been connected with that
9223 institution?

A. My professorship until three years ago was botany and horticulture, and the branches usually included in those two sciences, I had, at least in supervision, with certain assistants.

Q. How much teaching have you done in reference to biology or bacteriology?

A. Which?

Q. Both?

A. Well, my subjects have been all included under the first term—"Biology," as I understand it. I began studying bacteriology in 1877. I began teaching classes in bacteriology in 1885.

Q. How much time have you devoted to the teaching of biology which includes bacteriology, since that time?

A. All my time teaching and investigating.

Q. Have you ever delivered any course of lectures or lectured before special scientific societies upon these subjects?

A. Yes, sir, several times.

Q. Can you name some of the occasions?

A. The American Association for the Advancement of

Science, beginning in 1880, upon a bacteriological subject, and for a number of years subsequent to that for the same society.

About the same date I gave courses of lectures before the 9224 Natural History Society of Peoria, mostly on subjects connected with fungi and bacteriology. Beginning in 1878 and continuing almost to the present,—or more or less to the present—I have had annual papers in the proceedings of the American Microscopical society. I have during that time had some papers in the proceedings of the Royal Microscopic Society of London, England, and a great number on the more practical side of my general subject before state and American agricultural and horticultural associations.

Q. What was the general character of these various lectures and addresses?

A. The more technical ones were generally upon the diseases of plants caused by fungi and by bacteria. The more general ones upon matters connected with horticulture and forestry.

Q. What was the character of the address you delivered before the London Royal Society?

A. Bacteriological.

Q. When was that?

A. About 1886. This was a paper published; not an address.

Q. What scientific societies are you a member of?

A. American Association for the Advancement of Science, a fellow; American Microscopical Society, of which I am at present president; Western Naturalist's Society.

9225 Q. Any others?

A. No, I believe that is about all of this kind.

Q. What college degrees have you received, if any?

A. The institution at which I graduated gave no degrees. The Northwestern University at Evanston, some time in the seventies, conferred upon me the degree of Master of Arts, as an honorary degree. The old Chicago University upon a thesis bacteriological in kind, in 1881, conferred upon me the degree of Doctor of Philosophy—

Q. Ph. D.?

A. Yes. And the Northwestern University in 1893, I think it was, the degree of Doctor of Laws,—LL. D.—honorary.

Q. Have you ever made any special examinations of water for the purpose of ascertaining the presence of micro-organisms, if so, please state generally and specifically so far as you can remember?

A. I have never published anything upon the examinations of water of my own investigations until this article appeared in this report on Streams Examination. It has been my habit for at least twenty years, to make examinations, partly for the purpose of instruction in the subject; partly for the Illinois state authorities, in some instances the State Board
9226 of Health; partly for the state institutions—all of the state institutions, I think—I have made examinations of water for frequently—I mean all the public state institutions, insane asylums, penitentiaries, and so forth.

Q. Did you make any special examinations at the penitentiary of Joliet, for the prpose of determining whether tuberculosis infected the patients?

A. I did.

Q. Please state what that examination was?

A. In the spring of 1895 I was asked by Governor Altgeld to examine the penitentiary at Joliet for the matter of tuberculosis among the men confined there, and I devoted several days to the examination, especially of the sputum from persons suspected, of having this disease, and during the time I found the tubercle bacilli in the sputum of about 75 of the 1,600 men.

Q. Any action taken by the state authorities upon your report upon that subject?

MR. JEFFRIES: Objected to as irrelevant, incompetent and immaterial.

A. Yes, sir.

JUDGE SPRINGER: I do not desire to ask what the action was.

9227 MR. JEFFRIES: I move to strike out the statement of the witness to the effect that some action was taken, for the reason that it is immaterial.

JUDGE SPRINGER: Simply for the purpose of showing that this was an official matter for the benefit of the State authorities, that is all.

MR. JEFFRIES: I suggest that you have no right, except in a general way of the witness stating his qualifications and his attainments by degrees and otherwise, to corroborate his own evidnece, whether action was taken, for the purpose of strengthening the credibility of this witness' statements or testimony, is entirely incompetent and irrelevant, and contrary to all rules of evidence.

JUDGE SPRINGER: As this was an official matter I think it is competent to state that a report was made, and that some atcion was taken by the authorities for whom this investigation was made. That is all I desire to show.

Q. Did you make any other special examinations for state institutions?

A. No, sir; if I understand your question.

Q. Special examinations?

A. Of the state institutions; not otherwise than of the water supplies.

9228 Q. What did you do, if anything, in regard to their water supplies; what investigations did you make—I mean, in regard to the water supplies?

A. This was almost entirely upon the number of bacteria as revealed by the colony counts, and for the detection of Bacillus coli-communis.

Q. You mean of the water used by the patients in the in stitutions and by the students at the colleges?

A. Yes, sir.

Q. And the inmates of the prisons?

A. These waters in every case were sent to the University of Illinois. They were collected under my directions and usually in bottles sent by me for the purpose, but I did not go to the institutions to make the examinations.

Q. I understand you to say then, that the authorities—that they called upon you to make these investigations for the purpose of determining the character of the water used in the various institutions of the state?

A. That is the statement, yes.

Q. How long have you been engaged in that work?

A. Oh, it began about 1890,—I cannot give the exact date.

Q. Has it continued ever since?

A. More or less, yes.

9229 Q. Can you state approximately how many bacterial examinations of water you have made?

A. No, that would be impossible.

Q. You can give some idea, I presume, a great many of them, or a small number of them, you think?

A. Several thousands.

Q. And running through what period of years?

A. About thirteen years. I suppose I might make that longer, truthfully.

Q. State whether you made any bacterial examinations of the waters of the Illinois river, and its tributaries, and of the Chicago drainage canal in the years 1899 and 1900?

A. Beginning with May, 1899, I made a series of examinations from selected points in the course of that stream, and these were continued until October, 1900, and then in 1901, a series was made extending from October to December, inclusive.

Q. How many samples of water during that period of time did you examine bacterially?

A. These were for the most part weekly collections, from the stations arranged for by Professors Palmer and Jordan. There were two samples in each collection, and in the whole for the two years first named, there were 2800 of these samples; the number of entire cultures made from these samples
9230 amounted to about 7,000.

Q. State whether the samples of water which you examined during the two periods to which you have referred were those which were obtained by Professor Arthur W. Palmer, of the University of Illinois, and Professor Edwin O. Jordan, of the University of Chicago, during that time?

A. They were upon samples taken under their direction.

Q. And state whether those samples were procured at the times and places mentioned in the detailed reports of streams examinations by Professor Palmer?

A. They were.

Q. I call your attention, then, to tables 1 to 80, inclusive, which have been put in evidence by Professor Palmer and that are published in the book known as Streams Examinations, Sanitary District of Chicago.

A. I have them.

Q. Do you recognize the tables before you as the tables made by Professor Palmer and yourself?

A. I do.

Q. What part of these tables numbered 1 to 80, inclusive, was made by you?

A. The last two columns in each of the tables.

Q. What is the heading of those columns?

9231 A. The first one, "Presence or Absence of," as it is placed here, for short statement, "coli." Bacillus coli communis is what is referred to.

Q. And what is the heading of the last column to which you have referred?

A. Number of "Bacteria per Cubic Centimeter."

Q. State, please, what characters were used by you for the purpose of designating the presence or absence of the bacillus coli-communis in these tables, and whether any character was used to designate that you were in doubt as to whether the bacillus coli-communis was present or not?

A. The sign "plus" or an upright cross, is used to indicate the positive presence of this organism, as determined by me. The horizontal line, commonly called "minus," is used to indicate according to our test, the absence of this organism or group of organisms, and the interrogation point is used when the test could not be relied upon to indicate its presence, but the test did give some evidence of its being there; some of the tests, in other words, indicated its presence and others its absence.

Q. I see in some places, there are small dots, what do they indicate?

A. This means that for some reason no examination was made of the samples collected under those particular dates.

9232 Q. Please observe the first column, which indicates serial number, and the second and third columns which indicate the year of collection, and following those the dates in each year. Please state whether those were the serial numbers and the dates of collection and dates of examination of the samples of water which you examined for this purpose during that period?

A. The serial numbers published in this table are those attached to the samples by Professor Palmer. The series in all of this investigation extended from 1 on, the dates of collection were those upon the bottles.

Q. The tags?

A. The tags. And the dates of examination given here are those made by the chemical department, which in 99 per cent. of the cases were the same as the date of the examination by me. There are a few of these dates of examination which vary by one day from my own examinations.

Q. What do the figures in the extreme right hand column of these tables indicate?

A. These indicate the number of bacteria as revealed by our tests in a cubic centimeter of the water.

Q. Of the sample collected?

A. Of the sample that was collected, as I have explained.

9233 Q. Do these explanations which you have given apply to the whole series of tables, beginning with 1 and ending with 80, inclusive?

A. They do. If you will permit me to say, however, that there are some corrections, typographical corrections, to be made in these printed sheets.

Q. Have you made those yet?

A. I have in this copy of mine.

Q. I hand you now, Professor, tables numbered 1 to 80, inclusive, entitled "Streams Examination, Sanitary District of Chicago; Report of Arthur W. Palmer and T. J. Burrill, University of Illinois. Please state whether you identify those as the tables which were prepared by Professor Palmer and yourself?

A. These tables are prints from the manuscript copies prepared by us.

Q. If there are any errors in the copy you hold in your hands, as to the bacterial ascertainments, will you please note them and state them in evidence?

ERRATA AS TO BACTERIAL COUNTS IN TABLES 1 TO 80, ARE AS FOLLOWS:

9234 Table 1, serial number 5878, change "minus" to "no examination" in the next to the last column.

Same table, serial number 6187, change "no examination" to "plus."

Serial number 6333, change "plus" to "question mark."

Table 2, serial number 5790, change "plus" to "no examination."

Insert after serial number 5984, under date of collection, October 9th, and of examination October 10th, "plus" for coli determination, and for colony count, 1,320,000.

After serial number 6446, insert "collection December 11th;" examination same month, "12th;" interrogation mark for coli determination, and colony county, 925,000.

Table 3 for the serial number 6036 add "plus" for the coli determination, and 18,650 for the colony count.

Serial number 6280, change "minus" for coli to "no examination."

For serial number 6495 insert for the colony count, 23,000.

For table 4, after serial number 6024, insert "date of collection October 9th, examination October 10th, "plus" for the coli determination, and for the colony count, 1,175,000."

Table 8, in connection with serial number 5632, strike out
"minus" for coli determination, and 2,700 for colony
9235 count.

JUDGE SPRINGER: I want the record to note that Judge Hugh E. Crea of the Illinois bar, appeared as counsel in behalf of the state of Illinois, in association with General Hamlin.

THE WITNESS: (Continuing)

Table 9, in connection with serial number 5677, insert for coli determination "plus."

Table 15; in connection with serial number 5384, strike out the colony count of 120,000.

In connection with serial number 5739, change the indication "plus" for coli determination, to "no examination."

Next after serial number 5843, insert under date of collection September 19th, and examination September 21, "plus" for coli determination and 745,000 for colony count.

Table 21, insert after serial number 6257, under date of collection November 15th, and of examination November 16th, "minus" for coli determination, and "16,900" for colony count.

Table 22, serial number 5497, change for the coli determination, "plus" to "minus."

In connection with serial number 5542, change for colony count, "1450" to "580."

Table 28 in connection with serial number, 5815, change
9236 "2500" for colony count, to "7,500."

Table 32, in connection with serial number 5369, strike out the interrogation point for coli determination, and "48,500" for colony count. There was no examination there, the figuers got transposed from the year 1900.

Table 40, in connection with serial number 8529, strike out the determinations for coli and for colony counts.

And the same for the serial number 8586, and insert—and after serial number 8586, under dates of collecting October 8th, and of examination October 9th, "plus" for coli determination, and for colony count, "225,000."

Table No. 41, serial number 8594, the last on the page, change colony count "1,240,000" to "1,237,500."

Table 43, in connection with the three serial numbers, 8455, 8472 and 8490, for each of these serial numbers, place the colony count one space down in each case.

Table 49, serial number 7826, in the colony count, change "17,800" to "17,300."

Table 53, next after serial number 6740, insert under date of collection January 30, and of examination January 31, "plus" for coli determination, and "65,200" for colony count.

In table 55, in connection with serial number 7713, insert for coli determination "plus" and for colony count,
9237 "150,000."

Table 59, in connection with serial number 8,141, change "16,650" to "15,650."

Table 60, continued. This is the second continuation of that table. In connection with serial number 7848, change "minus" for coli determination to "no examination" and strike out for colony count, "560."

Table 60 concluded, in connection with serial number 8363, for coli determination, change "no examination" to "minus."

In connection with serial number 8470, change "minus" in coli determination to "plus."

In connection with serial number 8475, change "plus" to "minus" in coli determination.

In connection with serial number 8500, change in coli determination "minus" to "plus."

In connection with serial number 8512, change in coli determination "plus" to interrogation point.

In connection with serial number 8532, change the interrogation point to "plus."

Table 61 continued, in connection with serial number 7326, change in coli determination "plus" to "minus."

In connection with serial number 7350, change coli determination from "plus" to "minus."

In table 62, in connection with serial number 7627, change
9238 in coli determination "minus" to "plus."

In connection with serial number 8295, in coli determination, change "plus" to "minus."

In connection with serial number 8500, in coli determination, change "minus" to "plus."

Table 63, in connection with serial number 7326, in coli determination change "plus" to "minus."

Table 65, insert after serial number 7979, under date of collection July 25th, and date of examination July 26, "minus" for coli determination, and "1,300" for the colony count.

Table 66, in connection with serial number 6747, for coli determination change "minus" to "plus."

In connection with serial number 7055, in coli determination, change "plus" to interrogation point.

Table 67 in connection with serial number 6859, change for coli determination "minus" to "no examination."

Next after serial number 7980, insert under date July 25th for collection, and 26th for examination for coli determination, interrogation point. For colony count, "5,200."

9239 Table 69 in connection with serial number 7930 change for coli determination "no examination" to interrogation point.

Table 70 concluded, in connection with serial number 8278, in coli determination, change "plus" to "no examination."

Table 71, in connection with serial number 7965, insert "plus" for coli determination, and "28,000" for the colony count.

Table No. 71 concluded, in connection with serial number 8041, change for coli determination "minus" to "no examination."

In connection with serial number 8619, for coli determination, change "minus" to "plus."

Table No. 72, concluded in connection with serial number 8038 for coli determination, change "plus" to "no examination."

In connection with serial number 8480, change colony count from "1000" to "1800."

Table No. 75, in connection with serial number 7193, change "plus" to "minus" for coli determination.

Table 76 in connection with serial number 6763, for coli determination, change "plus" to "minus."

9240 Table 78, in connection with serial number 6824, in coli determination, change "plus" to "minus."

That is all.

Q. Professor, with the errors noted by you with reference to tables 1 to 80 of this series, please state whether the ascertainments for the presence of the coli group and for number of bacteria per cubic centimeter, are correctly stated?

A. They are.

Q. Have you made a table of monthly averages of colony counts based upon the detailed examinations found in these tables Numbered 1 to 80 inclusive?

A. I have.

Q. Please look at the table F, contained on two sheets, which I now hand you, and designated Table F, Streams examination, Sanitary District of Chicago, Sanitary Water Analyses, monthly averages of colony counts, report of T. J. Burril, University of Illinois, and state whether this table on two sheets contains the monthly averages of colony counts based upon the tables 1 to 80 to which you have referred?

A. They do sir; subject to one difference. This table of averages was based upon the regular weekly collections from the stream. When there were any extra collections, as
9241 there were at Grafton, and at the chain of rocks and other
places sometimes, those extra collections are not included in these averages.

JUDGE SPRINGER: I offer this table in evidence, to be known as Table F, two sheets, Streams Examinations, Sanitary District of Chicago, Sanitary Water Analyses, Monthly Averages of Colony Counts, report of T. J. Burrill, University of Illinois.

MR. JEFFIIES: I object to the table being offered in evidence for the reason that it does not show the average number of colony counts found at various points in the Illinois river and the canal during all the months of the two years in question, to-wit, 1899 and 1900, and for the further reason that comparative results are only shown for the months of June, July, August and September, which are recognized as summer months, and no comparisons were made for the winter months. I therefore object to it for the reason that the results so obtained from the various analyses are not comparable with each other, and that the results obtained for the years, to-wit, 1899 and 1900, are not comparable.

JUDGE SPRINGER: I desire to state in behalf of the defendants, that the table of averages now offered in evi-
9242 dence, speaks for itself, and indicates upon its face exactly what it is intended to represent; that the objection of counsel merely goes to the weight of this table as evidence and not to its competency.

MR. JEFFRIES: I agree with counsel that the tables show for themselves, but I insist that the comparative averages for the two years are not comparable as shown by the tables themselves, and therefore are not competent.

JUDGE SPRINGER: That is a question for the Court to determine and not for counsel.

THE WITNESS: The table is as follows:

TABLE F.

STREAMS EXAMINATION—SANITARY DISTRICT OF CHICAGO.

SANITARY WATER ANALYSIS—MONTHLY AVERAGES OF COLONY COUNTS.

Report of T. J. BURRILL, University of Illinois.

YEAR.	LOCATION.	SOURCE OF WATER.	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.

9245

ERRATA.

Q. State whether the table as printed above contains any errors and if so, please note them?

A. They do. The number specified for the collection at Kedzie Avenue in June, 1900, here given as 377,000 should be 377,500.

The number given under date of December, 1899, as 12,757, should be 12,787. These are all the corrections.

Q. Professor, please state whether the errata which you have indicated as appearing in tables Nos. 1 to 80 inclusive, were taken into consideration in making up the table of averages contained in table F, just put in evidence?

A. These averages were made from the numbers as now corrected in tables 1 to 80.

Q. Will you please state briefly and generally what this table F of averages shows?

A. This table is intended to show the average number of bacteria as shown by all the determinations from the samples regularly collected each week for the different months of 1899 and 1900, during which the examinations were made.

9246 Q. Will you state, professor, in what manner you plated for these colony counts?

A. The plating for colony counts was made upon standard nutrient agar; this was made from an infusion of butcher's meat, and with phenolphthalin as an indicator was neutralized to represent ten on Fuller's scale or one per cent of normal of acid. We took pains to have the medium made sometime before its use because we found less trouble from it in counting the colonies. There were less over-growths when it was so kept. A cubic centimeter, diluted if necessary beforehand, of the water, so as to have from our experience, from 50 to 100 colonies on a plate, was placed in a test tube of the melted agar, well shaken up and immediately poured into the plates called Petri dishes; these after some preliminary trials were kept in a constant temperature room in the basement of a large building, at 20 degrees centigrade, and were left a uniform time of ten days before counting. In the counting a lens was used when this was helpful.

Q. Is this the usual method for making these ascertainments?

A. It is, sir, except that very frequently gelatin is perferred instead of agar for the purpose. I will say that in our tests, in the examinations of this particular water we found our results more uniform with the use of agar, for the extended
9247 period of ten days, than we could get with gelatin at the maximum period of about four days. The number of colonies were in many instances a little less when agar was used than when gelatin was used in the best manner, but the results proved more uniform, hence the selection of the agar instead of the gelatin.

Q. What attention did you give in making these bacterial examinations for the purpose of ascertaining the presence of the bacillus coli communis?

A. This work was begun in May, 1899, during that month preliminary experiments were made with several methods for detecting this organism or group of organisms. From out previous experience and from these tests, a routine method was adopted, somewhat as follows:

A culture medium made up of five grams of Liebig's meat extract, ten grams of chemically pure lactose; one gram of pure carbolic acid crystals, and 1000 cubic centimeters of distilled water, to which was added sufficient solution of litmus to give it a distinct bluish, purplish or violet color. This was our preliminary culture medium. A cubic centimeter of the water to be examined was placed in each of two tests tubes containing about ten cubic centimeters of this medium, and this was placed
9248 in an incubator at 38 degrees centigrade for 48 hours. Our previous results had shown that when the bacillus coli-communis was present in the water, that this litmus colored medium was changed to a reddish color within the time mentioned, under the conditions in which it was placed. If no such change occurred in this medium, a negative result was at once interpreted, though in some cases of doubt the tubes were left a longer time in the incubator, to determine the results. If the medium became red in color, then plating was resorted to in nutrient gelatin, containing the same quantity of lactose and carbolic acid as in the former medium, with litmus to give it the violet color. After 24 hours incubation at about 22 to 23 degrees centigrade, attempts were made to select colonies from these plates, showing the characteristics of bacillus coli-communis. Microscopic

examinations were made from these selected colonies, and transfers were made from such selected colonies to broth made sugar-free by previous culture for about sixteen hours, of Bacillus coli-communis, and subsequently filtered and sterilized for indol tests; also in two per cent glucose broth for use in ferment tubes, and also into sterilized milk. If in these different media 9249 the reactions characteristic of the bacillus coli-communis were found, a positive interpretation was made for the presence of these organisms; if most of them failed, a negative determination was made. If some of them indicated the presence of the organism and some indicated its absence, a question mark was placed as the result of the finding.

I may say in this connection that I have to present photographs of fermentation tubes thus handled, as we found them after growth from the selected colonies mentioned before.

These photographs, two of them, each give the conditions of things for one week's tests, and show pretty conclusively that the colony examination usually are the *bacillus coli-communis.* We took as an arbitrary standard of determination, 30 to 60 per cent of gas in the closed arm of the fermentation tube, as indicative of the bacillus coli-communis, and if there proved to be more or less than this, we assumed that the organism under test was not this one.

JUDGE SPRINGER: I present these photographs at this time, as defendants' Exhibit Nos. D and E for identification, to be incorporated hereafter in the testimony if counsel on either side so desires, and to be kept by the Commissioner for reference by counsel at any time. The one containing 62 flasks 9250 being marked Defendants' Exhibit D, and the one containing 79 flasks being marked Defendants' Exhibit E.

JUDGE SPRINGER: Will you proceed with this explanation professor?

A. I may say that in this method of procedure, we had more variation in the indol test than in any others, and that we were obliged more frequently to exercise our judgment in this one respect than in any other, as to what mark should be given for the determination.

Q. Will you please consider briefly, the tables to which you have testified, which contain the colony counts as indicated by you and point out the differences which exist in the bacterial content of these waters in the different portins of the stream?

A. The difference in colony counts for different portions of the stream is very marked, and while there is considerable variation for each point, there is for all of our tests very striking agreement in the greater number existing in the course of the stream near its head at Bridgeport, amounting to several millions in a cubic centimeter, and then a more or less gradual decrease to Peoria, and from Ottawa to Peoria, this decreased number is exceedingly marked.

Q. Please point out the differences which are indicated between the colony counts at Bridgeport and Averyville, for the period in question?

9251 A. The colony counts from the tests made from samples taken at Bridgeport on November 7th, 1899, were 4,790,000; November 15th, 1,960,000; November 21st, 3,920,000; November 29th, 315,000, with the average for the four tests of 2,497,000.

At Averyville for the same time, the counts were respectively, 550, 1,100; 1,200; 2,800; an average for the four tests, 1,640.

Q. Now for the year 1900 what do those counts show for these two places?

A. And for the year 1900 in April at Bridgeport, on the 3rd of that month, 5,300,000; on the 10th, 3,725,000; on the 17th, 11,200,000; on the 25th, 3,925,000, with an average for the four tests of 6,037,500.

While at Averyville for the same times, the counts were 28,000; 17,000; 5,500; 1,850, and with an average for the four of 13,087.

Q. In your examinations have you noted any increase in the quantities of polluting matter as sewage from the cities of Peoria and Pekin, and if so, please state what your colony counts indicate in regard to those for the two years mentioned?

A. The colony counts showed a great increase in number of bacteria after the pollutions were received by the river
9252 from Peoria and Pekin. As an illustration of this I will say that in 1899 on November 1st, there were found at Pekin, 2,780,000 bacteria per cubic centimeter; on November the 9th, 170,000; on November 16th, 145,000; on November 24th, 95,000; with an average for the four tests of 797,500.

For the same times at Beardstown, which is 56 miles further down stream, the colony counts were respectively, 6,500; 21,500; 7,150; 35,200, with an average for the four tests of 17,590, for the year 1900.

For July 6th, 1900, there were at Pekin, 38,500; for July the 12th, 555,000; July 19th, 370,000; July 26th, 220,000; with an average of 295,875.

While at Beardstown for the same times there were respectively, 3,500; 4,000; 3,000; 3,600; with an average of 3,700.

I should say that in order to make this tabular statement, the dates given sometimes vary by one day, for one or the other of the numbers given, because the collection was not always made on the same day.

Q. How much greater do these figures show for each period, was the number of bacteria per cubic centimeter at the respective places?

9253 A. The averages in the last figures show respectively, 45 and 71 times as many bacteria in the water at Pekin as at Beardstown, though the distance is 56 miles and the time required for the flow of the water 24 hours.

Q. Please state, professor, whether you prepared any graphic plates based upon the tables of data contained in pages 1 to 80 of the series in question, illustrating graphically the conditions shown by those tables?

A. I did not directly from these tables, but I did from the monthly averages that are exhibited in table F.

Q. And that is based upon what data?

A. That was based upon data as given in tables 1 to 80.

Q. Please examine the plates which I now show you and state whether these plates were prepared by you?

A. These plates were prepared by me.

Q. What do they show, briefly?

A. They show in a graphic presentation, what is shown in figures in table F, which is based upon the detailed data contained in tables 1 to 80 of this series.

JUDGE SPRINGER: I will offer these plates in evidence, being plates numbered 21 to 28 inclusive, and to be known
9254 as plates 21 to 28 inclusive, of the bacteriological laboratory of the University of Illinois.

Plate 21 is as follows:

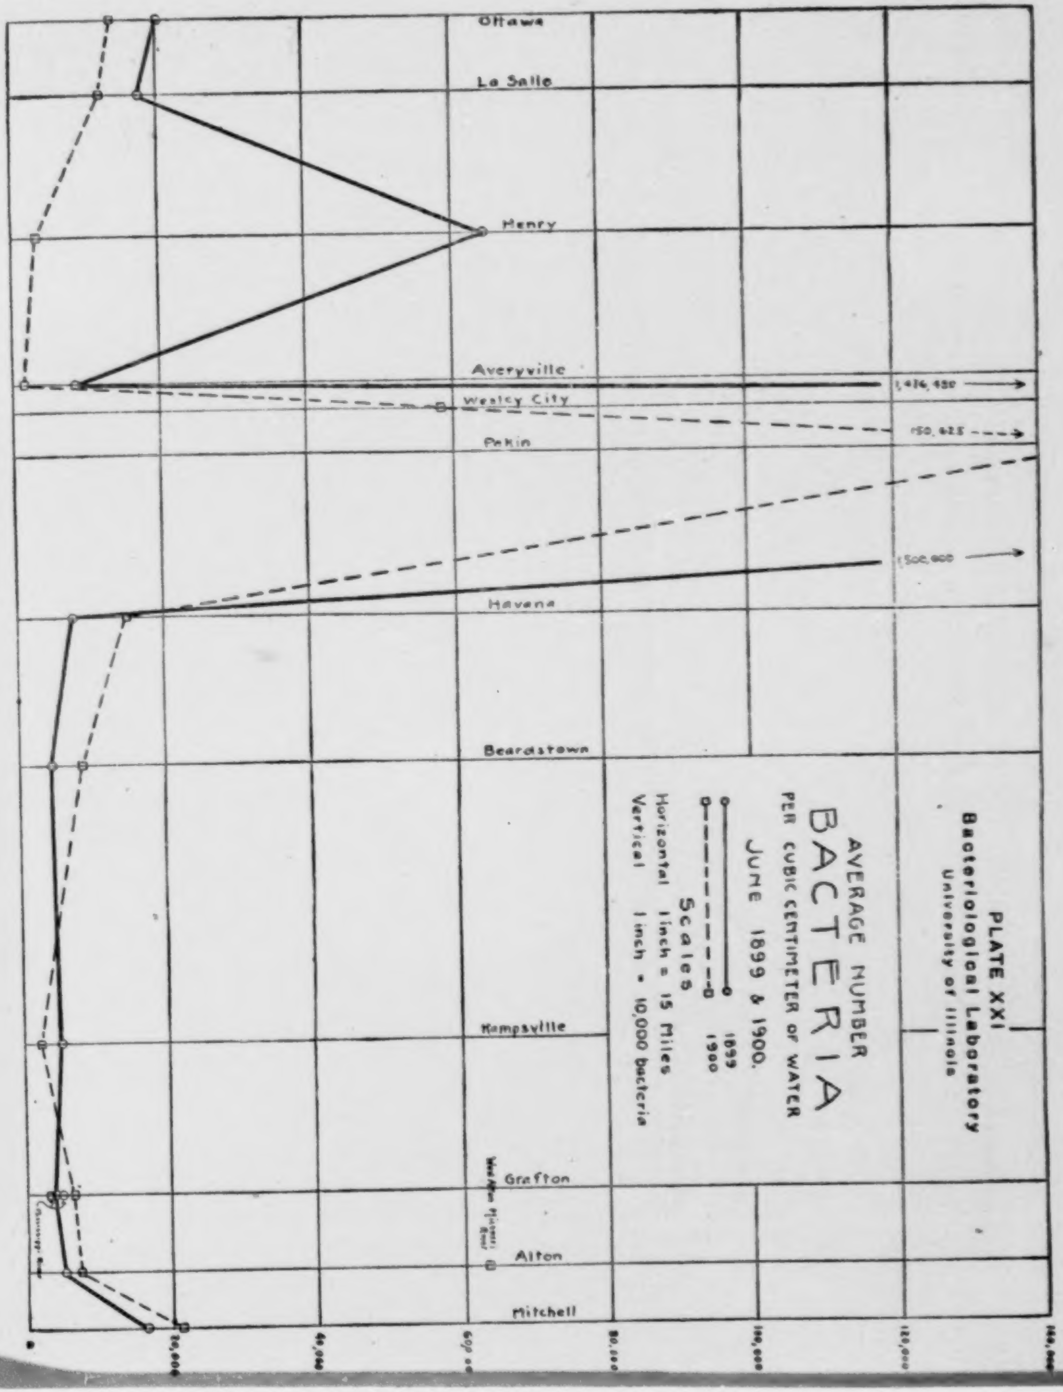

PLATE XXI
Bacteriological Laboratory
University of Illinois

AVERAGE NUMBER
BACTERIA
PER CUBIC CENTIMETER OF WATER
JUNE 1899 & 1900.

9256 Q. JUDGE SPRINGER: Please explain professor, what is shown by plate 21, which is put in evidence?

A. This shows the average number of bacteria per cubic centimeter of water for the month of June, 1899 and 1900, according to all our tests made for these dates.

The whole black line indicates the number forJune, 1899.

The broken line or the line made up of short straight pieces, for the month of June, 1900.

This plate shows the tests made from Ottawa to Mitchell, otherwise known as the chain of rocks, opposite the intake tower of the St. Louis waterworks.

The earlier tests (those from samples taken above Ottawa) were not indicated on this plate because the numbers are so great that they could not be shown on this scale. It will be noticed that at Ottawa the number was 20,000; at LaSalle it was about 18,000; at Henry it was about 64,000; at Averyville it was about 9,000; at Wesley City the number was so great that it could not be shown on the plate. The lines were stopped near the upper part of the plate and the number inserted, 1,476,480. And at Pekin for the same reason the line does not show the number, but the figure is put in, 1,500,000. Now the number drops quickly to Havana, where it is shown to be about
9257 8,000; at Beardstown about 5,000; and at Kampsville about 6,000; and at Grafton about 5,000 again. At Alton about 6,000; and at Mitchell as named on this plate, about 17,000.

It ought to be said that the term "Mitchell" is used here as the nearest railroad station to the place otherwise called the Chain of Rocks. Now for June in the year 1900, at Ottawa, the number is about 14,000; something a little less at LaSalle, and 3,000 at Henry, and 1,500 at Averyville, all of which is below that of 1899, and then at Wesley City, six miles below Averyville and below the reception of the Peoria sewage, 59,000 and at Pekin, 150,625; and at Havana, about 15,000. At Beardstown, 8,000; at Kampsville, 2,000; at Grafton, Illinois river about 7,000; and at Alton, 8,000; and at Mitchell, 21,000.

I wish to say that the showing is for 1900, less than for 1899 in the first part of the stream as here indicated, and more for some distance after Havana, less at Kampsville and more again at Grafton, Alton and Mitchell.

There is further shown on this plate the colony counts for the Mississippi river at Grafton, by a little separate circle, showing about 5,000 for 1899, and 3,000 for 1900; that is, the 9258 showing for the Mississippi during this comparison, is a little lower in each case than for the Illinois river.

ADJOURNED until 2:00 P. M. same day, Wednesday, November 25th, 1903.

9259 2:00 P. M., Wednesday, November 25th, 1903. Continuation pursuant to adjournment.

Present, the Commissioner and same counsel representing the respective parties.

THOMAS J. BURRILL,

resumed the stand for further direct-examination by Judge Springer, and testified as follows:

Q. Professor, I now call your attention to plate 22 of this series. Will you please explain what is shown or illustrated by this plate?

A. Plate 22 shows the same thing as plate 21, but represented in a different way, and has in addition the showing for the Illinois and Michigan canal at Lockport; for the Desplaines river at Joliet, and for the Illinois river at Morris. In plate 21, the presentation is shown by oblique lines; in plate 22 the exhibit is made by perpendicular lines.

Q. Please explain the first column on the left hand side,—it seems to be represented by three lines.

A. The solid black line exhibits the counts made for the 9260 month of June, in 1899, and the open line or the light colored line shows the counts for this month in 1900. The total number represented on the perpendicular line is 1,400,000 as seen at the upper right hand corner.

Q. And for the three lines then what would that indicate?

A. Now the entire length of the first black line goes twice across the plate, representing 2,800,000, and again rising to 1,090,000, which, added to the 2,800,000 makes 3,890,000. The light line shows 1,000,000.

Q. Those two counts indicate the differences between the colony counts for the time indicated, for the month of June, 1899, the year before the opening of the canal, and the other column indicates the number found for June, 1900, the year after the opening of the canal?

A. That is correct.

Plate 22 is as follows:

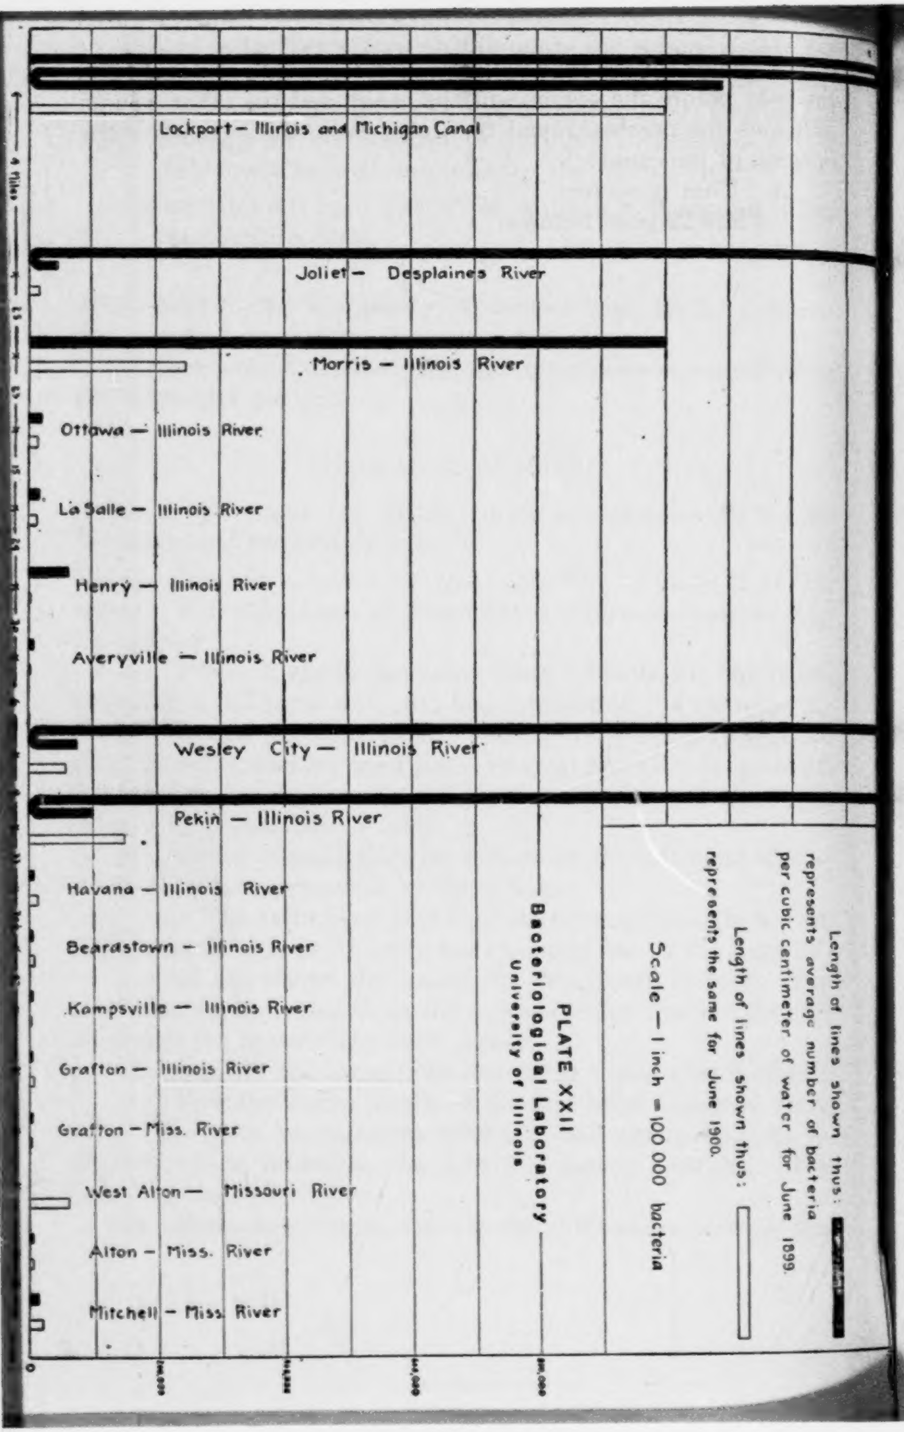

PLATE XXII

Bacteriological Laboratory

University of Illinois

9262 Q. I call your attention professor now to plate 23 of this series. Please explain what is shown or illustrated by this plate?

A. Plate 23 shows the average number of bacteria per cubic centimeter as determined by the tests during July, in 1899, and also for the same months in 1900. The solid black line, exhibits the number for 1899, and the broken line for 1900 of this month.

It will be seen that for the year 1899 we started Ottawa with about 9,000 bacteria. At LaSalle the number sinks to about 7,000, at Henry it rises again to about 22,000; at Averyville it is a little over 9,000; and at Wesley City the line, if drawn would extend beyond the plate, and the figures are given to indicate 3,925,000, and at Pekin, 737,625. At Havana the number rapidly decreases to about 6,000 and at Beardstown to about 1,000. Again at Kampsville it rises somewhat, to about 3,000; slightly sinks again at Grafton, to about 2,500, for the Illinois river, and at Alton to something less than 2,000, while at Mitchell it rises to about 6,000.

Q. Please explain the condition of the Mississippi river at Grafton as indicated by that line?

A. The Mississippi river at Grafton,—the number of
9263 colonies from tests of the water in the Mississippi river is
indicated by the small circle as less than 1,000 for this
year.

Q. And at West Alton in the Missouri river?

A. And at West Alton, it was 20,000. I may say that these places are not connected by slanting lines because they were not on the direct course of the stream.

Q. Now for the next year; for July, 1900?

A. For July, 1900, we have commencing at Ottawa, from 2,000 to 3,000; at LaSalle, 3,000 to 4,000; at Henry, 40,000; at Averyville about 4,000; at Wesley City, about 96,000; at Pekin 313,375; and at Havana 23,000; at Beardstown about 4,500; at Kampsville 2,000; at Grafton about 4,000; at Alton about 6,000 and at Mitchell 26,000.

Q. Is the Missouri River indicated there?

A. The Missouri river for this year at Grafton, is indicated.

Q. I mean West Alton—the Mississippi river I mean to say?

A. Missouri river is not represented for 1900.

Q. Or the Mississippi river at Grafton?

A. Yes, the Mississippi river at Grafton is about 4,000. Right between the indication for the Illinois river at Grafton for the two years.

Plate 23 is as follows:

80,000
100,000
120,000
140,000

9265 Q. I now call your attention to plate 24 of this series. Please explain what is indicated by this plate?

A. Plate 24 is another way of showing what was contained in plate 23, and with the addition of the exhibit for the Illinois and Michigan canal at Lockport, for the sanitary canal at Lockport, for the Desplaines river at Joliet; and for the Illinois river at Morris. In this plate the indication is made by vertical lines, with the black solid lines for 1899 and the open light lines for 1900.

Q. What is indicated by the line for 1899 at Lockport, the Illinois and Michigan canal?

A. This shows about 5,320,000.

Q. For July, 1899?

A. For July, 1899.

Q. What is shown for the same month in 1900?

A. 740,000.

Q. Now the Desplaines river at Joliet, what does that indicate?

A. For 1899 the black lines show about 2,850,000.

Q. And what for the same place for the month of July, 1900?

A. And for 1900, about 170,000.

Q. What is shown at Morris?

A. At Morris, for 1899, the indications are that there were about 930,000 and for the year 1900, a little less than 45,000. 9266

Q. What is shown at Averyville?

A. At Averyville the exhibit shows very few numbers for both years, about 10,000 for 1899 and rather less than 5000 for 1900.

Q. What does the next column indicate—there are three columns there?

A. That is for Wesley City. Do you wish that?

Q. Yes?

A. For Wesley City the dark lines show about 3,925,000 for 1899, and for 1900 a little less than 100,000.

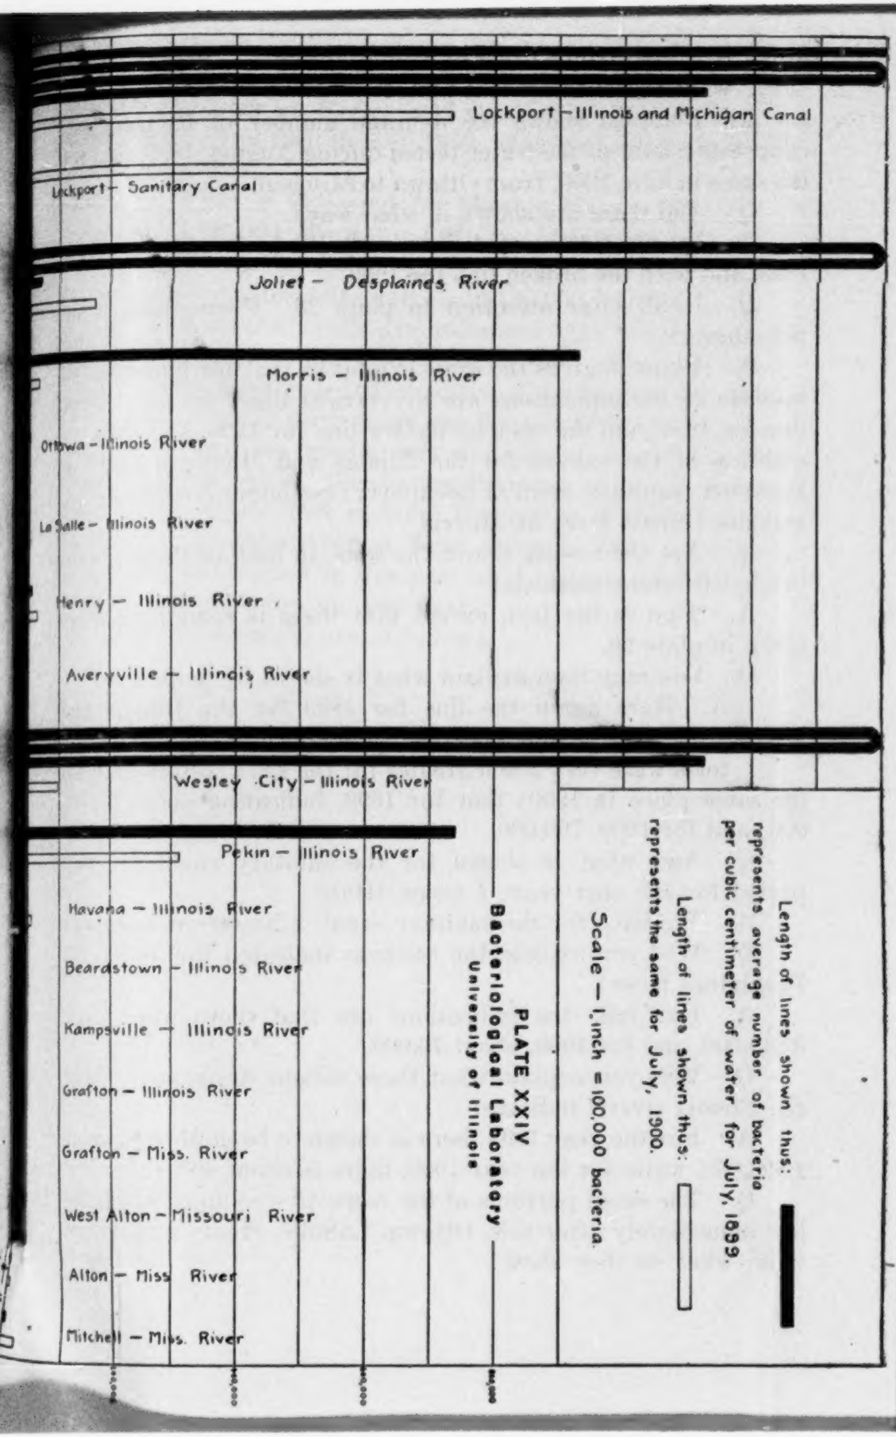
Q. What is the result as to Pekin?

A. For 1899, the indications are that there were about 740,000; and for 1900, 315,000.

Q. What are the ascertainments for the remainder of the river down to Mitchell, or the chain of rocks?

A. From Havana on through the course of the stream the indications show very clearly that the number of bacteria were compared with those already mentioned, exceedingly small.

Plate No. 24 is as follows:



Length of lines shown thus: ■ represents average number of bacteria per cubic centimeter of water for July, 1899.

Length of lines shown thus: ☐ represents the same for July, 1900.

Scale — 1 inch = 100,000 bacteria.

PLATE XXIV

Bacteriological Laboratory

University of Illinois

9268 Q. I call your attention now to plate 25. Please explain what is shown by that plate?

A. Plate 25 shows the average number of bacteria per cubic centimeter of the water tested during August, 1899, and for the same month, 1900, from Ottawa to Mitchell.

Q. And these are shown in what way?

A. By black connected lines, with the heavy dark line for 1899, and with the broken line for 1900.

Q. I call your attention to plate 26. Please state what that shows?

A. Plate 26 gives the same exhibit as that for plate 25, but in plate 26 the indications are by vertical lines, the solid black line for 1899, and the open or lighter line for 1900, and with the addition of the exhibit for the Illinois and Michigan canal at Lockport; sanitary canal at Lockport; Desplaines river at Joliet, and the Illinois river at Morris.

Q. Are the results shown the same in both of these plates, but by different methods?

A. That is the fact, except that there is something more given in plate 26.

Q. You may then explain what is shown by plate 26?

A. Here again the line for 1899 for the Illinois and 9269 Michigan canal at Lockport show that the number of bacteria were very much greater for the same waters than for the same place in 1900; that for 1899, indicating about 3,240,000; and for 1900, 790,000.

Q. And what is shown for the sanitary canal for that period for the next year; I mean, 1900?

A. We have for the sanitary canal, 1,200,000 at Lockport.

Q. Will you explain the columns indicated for Joliet, the Desplaines river?

A. For 1899 the indications are that there were about 3,240,000, and for 1900, about 70,000.

Q. Will you explain what these colums designated "Morris, Illinois river" indicate?

A. For the year 1899 there is shown to be at Morris, about 4,890,000, while for the year 1900, there is about 40,000.

Q. The small portions of the respective columns which follow immediately after this, Ottawa, LaSalle, Henry and Averyville; what do they show?

A. They show that for this month of August the colony counts from Ottawa to Averyville inclusive were very low, but greatest for 1899 at Henry. At Averyville the number was slightly greater in 1900 than in 1899, while at LaSalle they were about equal.

9270 Q. What is indicated for Wesley City?

A. 2,360,000, about, for 1899, and 50,000 for 1900.

Q. And what for Pekin?

A. 1,940,000 for 1899, and about 145,000 for 1900.

Q. The counts which are indicated thereafter beginning with Havana, and ending with Mitchell, show what condition?

A. Here again it is indicated that the comparative number of bacteria found is very much less than at Wesley City and at Pekin, but upon the whole, very similar to those found from Ottawa to Averyville. The largest number represented in this section of the plate, that is, from Havana to Mitchell inclusive, was, in the Missouri river at West Alton, in 1899. The showing is not far different in this part of the plate, otherwise than as mentioned, between the two years.

University of Illinois

9273 Q. I call your attention now to plates 27 and 28 of this series. What are represented by these plates?

A. Plate 27 shows in a graphical way the average number of bacteria found at the collections taken from Ottawa to Mitchell in September, 1899 and 1900; and plate No. 28 is an exhibit of the same in vertical lines, with the addition of the showing for the Illinois and Michigan canal at Lockport, the sanitary canal at Lockport, the Desplaines river at Joliet, and the Illinois river at Morris.

Q. What is shown by these two plates as to the condition of the water at Lockport for this month of September, 1899?

A. Plate 28 shows that the average number of bacteria for September, 1899, was a little over 700,000, while for 1900 the number is 3,200,000.

Q. That is in the Illinois and Michigan canal at Lockport?

A. In the Illinois and Michigan canal, yes sir.

Q. What is shown for the sanitary canal for 1900 at Lockport, and the Chicago drainage canal?

A. There are about 650,000.

Q. And the Desplaines river at Joliet, what is shown?

A. The showing of this plate for the Desplaines river at Joliet indicates that the number of colonies found for this month was very much less than for the preceding months for
9274 which exhibits have been given amounting in 1899 to about 220,000 and for 1900, to about 210,000.

Q. What is indicated with reference to the waters at Morris in the Illinois river?

A. At Morris, the number for 1899 is seen to be about 2,190,000 while for 1900 it was about 640,000.

Q. Explain the succeediing indications on this plate?

A. On this plate the number at Ottawa is seen to be somewhat greater than in the previous exhibits, and about the same in the two years, a little greater in 1899, reaching about 40,000. At LaSalle, decreasing to about 10,000, with a little more in 1900, and about the same at Henry for 1899, but rising in 1900, to 130,000, and sinking again at Averyville to about 3,000 for each year. At Wesley City the showing for September is much less than for the preceding months, as given, amounting to 490,000 for 1899, and 280,000 for 1900, and a similar statement can be made in regard to the number at Pekin for 1899 since it is a little less than 400,000; but for 1900 the representation indicates that there were 1,070,000 at this place.

At Havana there were also more for 1900, there being about 70,000, while for 1899 there seems to be less than 2,000.

During the rest of the course of the stream the numbers are again comparatively very much reduced, but are more
9275 than elsewhere from the Missouri river at West Alton,
where the number seems to be about 20,000 and upwards for 1899 and 25,000 for 1900.

At Alton for this year the number is slightly greater for 1900 than for 1899. At Mitchell the numbers were about equal for the two years.

Tables 27 and 28 are as follows:

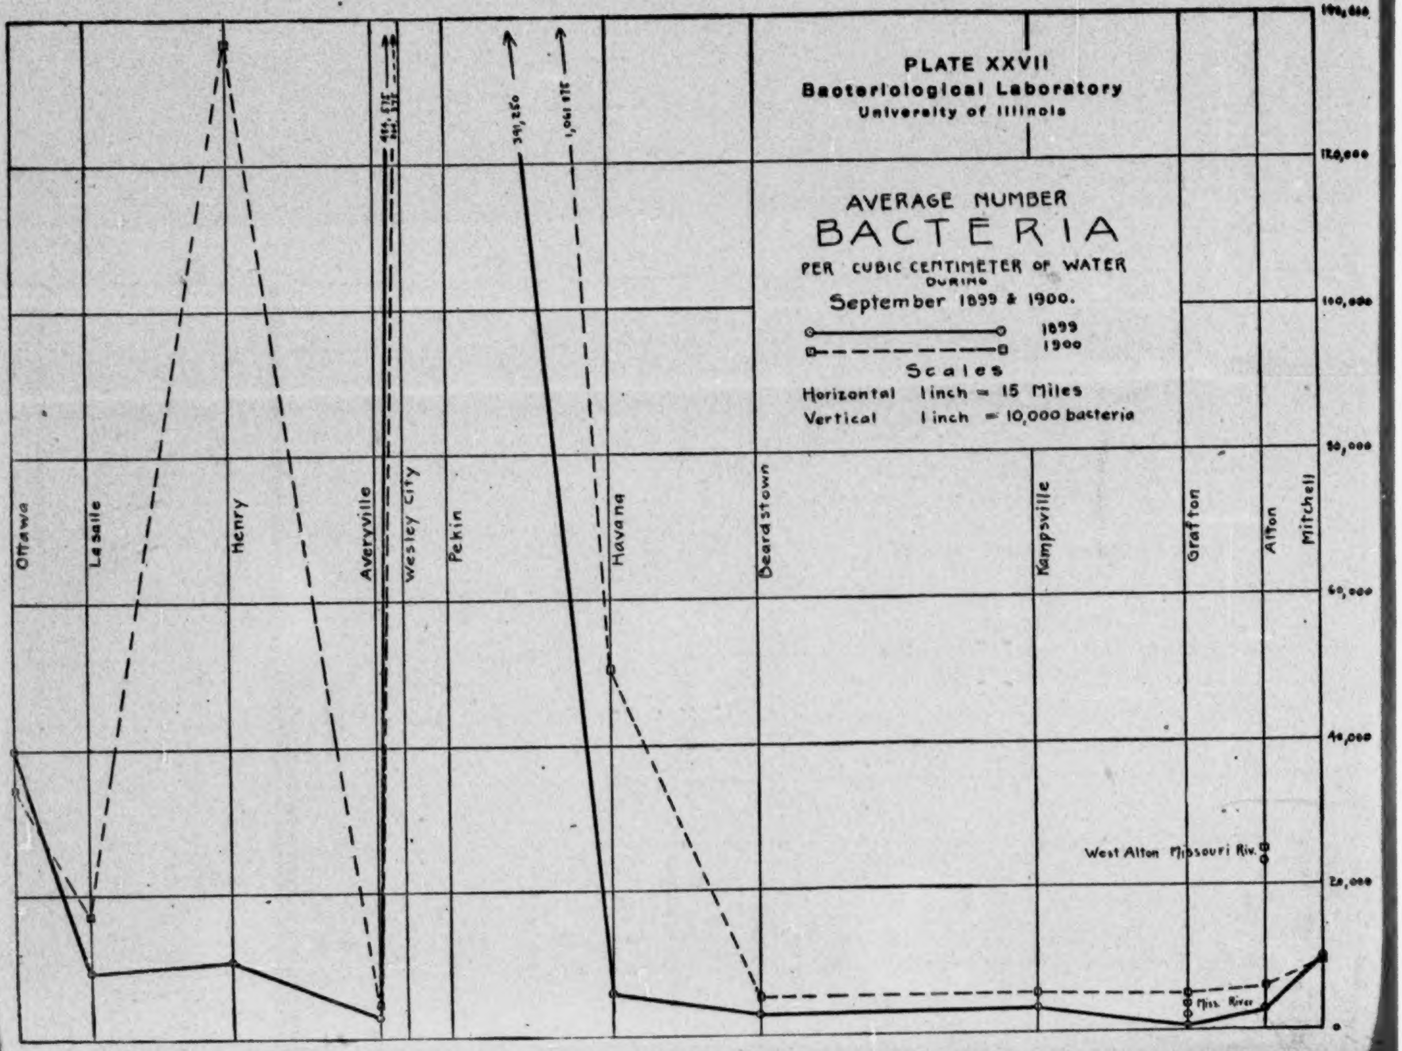

PLATE XXVII
Bacteriological Laboratory
University of Illinois

AVERAGE NUMBER
BACTERIA
PER CUBIC CENTIMETER OF WATER
DURING
September 1899 & 1900.

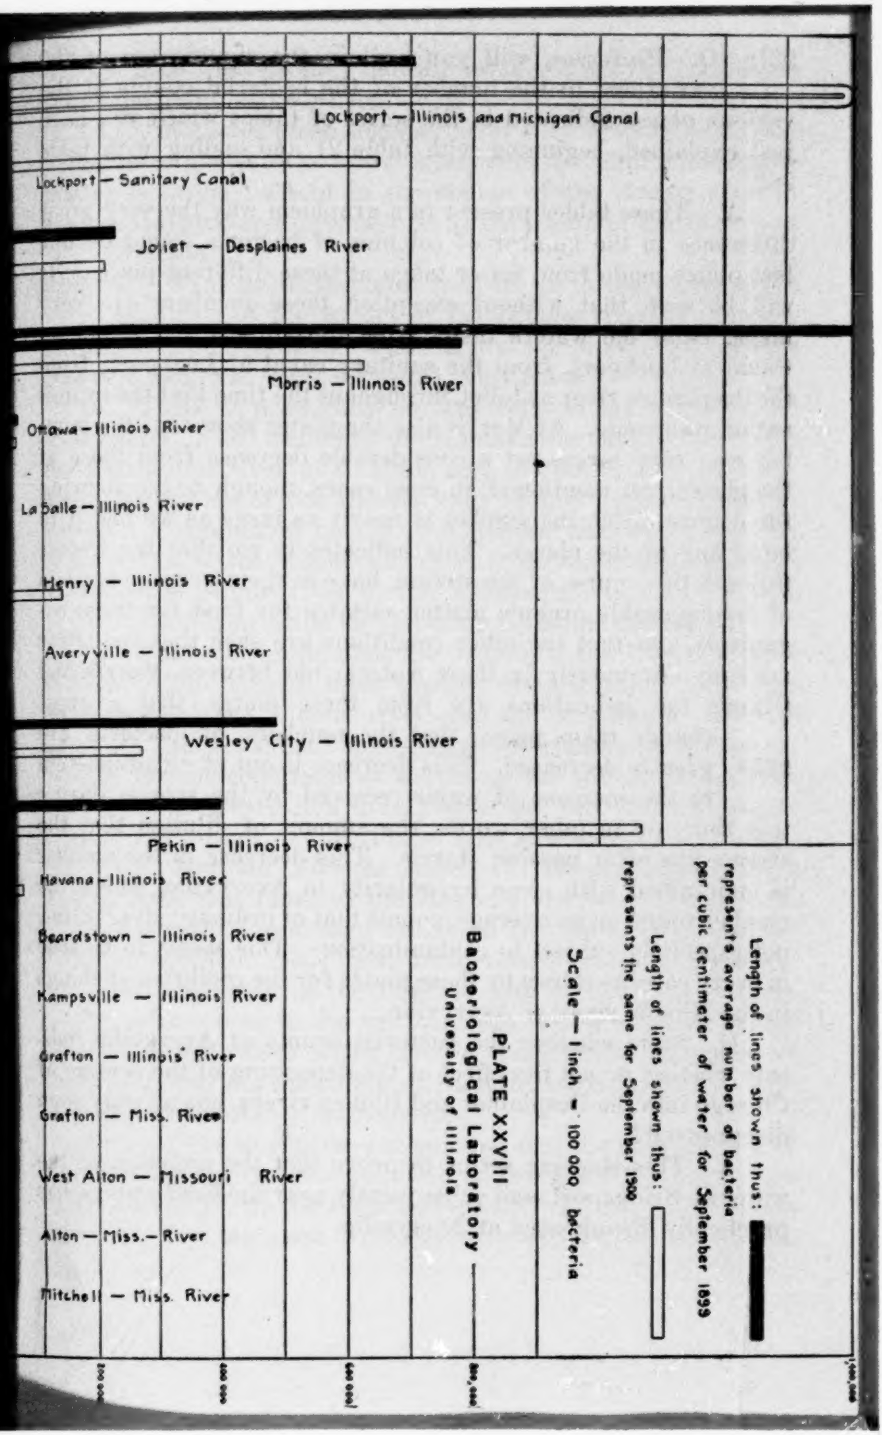

PLATE XXVIII
Bacteriological Laboratory
University of Illinois

9278 Q. Professor, will you explain the significance of the variations in the number of the bacterial counts at the various places indicated in the series of tables which you have just explained, beginning with table 21 and ending with table 28?

A. These tables present in a graphical way the very great difference in the number of colonies of bacteria found on our test plates made from water taken at these different places. It will be seen that without exception these numbers are very large, from the waters taken from the Illinois and Michigan Canal at Lockport, from the sanitary canal at Lockport; from the Desplaines river at Joliet, throughout the time that the examination was made. At Morris also the plates show that the number was very large, yet a considerable decrease from those at the places just mentioned, in most cases, though in the showing for August, 1899, the number is nearly as large as we find it to be at any of the places. This indicates to me that the waters through this course of the stream, have in them great quantities of decomposable organic matter suitable for food for these organisms, and that the other conditions are such that the latter multiply enormously in these waters; but between Morris and Ottawa the indications are from these plates, that a great change takes place; that the numbers of bacteria are 9279 greatly decreased. This decrease is out of all proportion to the increase of water received by the stream during this time, or in other words, the amount of dilution that the stream has after passing Morris. This decrease in the number is maintained with some irregularity to Averyville, where the number found on an average, equals that of ordinary river water, not especially subject to contamination. This seems to be true in every case, as shown by these plates for the condition of things in the Illinois river at Averyville.

Q. State whether the bacterial counts at Averyville indicate whether or not the effect of the depositing of the sewage of Chicago into the Desplaines and Illinois rivers, has already soon disappeared?

A. This showing seems to prove that the pollution of the water at Bridgeport, and subsequently near the head waters, has practically disappeared at Averyville.

Q. And what do they indicate further down at Grafton, so far as the additional contribution of pollution is concerned?

A. The plates taken together show very conclusively great pollution of the stream below Averyville, but that the organic matter is largely absent in the course of the stream after it reaches Havana, and especially so at the mouth of the Illinois at Grafton.

9280 Q. What do these plates indicate as to the comparative condition of the waters of the Illinois river at Grafton, the Mississippi river above Grafton, and the Missouri river just above its mouth at the place called West Alton?

A. There is practically no difference so far as shown by these plates, in the waters of the Illinois river before they enter the Mississippi river at Grafton, and of the Mississippi river above the mouth of the Illinois river at this place. There is, however, a continuous exhibit of a greater number of bacteria in the waters of the Missouri river at West Alton than there are in either the Illinois river or the Mississippi river at Grafton.

Q. What conclusion do you draw from this difference?

A. I can only infer that the waters of the Missouri river at West Alton have in them greater contamination than have the waters of the Illinois river and the Mississippi river at Grafton. I do not think I have enough information of the special reasons for the conditions as shown for the waters of the Missouri river at West Alton to be able to say why the pollution is greater there than in the Illinois and Mississippi at Grafton. I will say, however, that the records of temperature in these waters show that those of the Missouri are for the most part somewhat lower than are those for the Illinois and the 9281 Mississippi. This lower temperature probably has something to do with the lessened rate of decrease in these colder waters, than in the warmer ones, for it must be understood that the waters which have a temperature favorable to the growth and multiplication of bacteria, clear up sooner than those not so favorably conditioned.

I would like to express my opinion, that the greater part of this clearing up from the pollution of the water is directly due to the agency of the bacteria themselves, and this will explain why I say that the more favorable the condition for the growth and multiplication of the bacteria the quicker the pollution disappears.

Q. Will you explain what is the effect produced by these bacterial agencies?

A. The bacteria have in general, as a source of food, dead organic matter. They in this respect have the same influence upon this organic matter as do animals, reducing the compounds from their higher or complicated states to less and less complex conditions, until finally the hydro-carbons are so reduced to water and carbon dioxide and the proteid matters, to ammonia or still further, to nitrites and nitrates ultimately; in other words, the principal role of bacteria in this regard is exactly opposite to that of green vegetation,—the latter are concerned in building up organic compounds from the simpler 9282 states, and the bacteria are reversing the process and ultimately the result is that the operations of the green vegetation are exactly destroyed; and we start over again with the condition of the substances in which we had them at first.

Q. In other words, the bacteria operate upon dead organic matter whether animal or vegetable, and reduce such matters to their original elements, and these original elements are in turn taken up by the chlorophyl vegetation and restored again to the form of vegetable matter, and vegetable matter being used as the food for animals, produce again animal matter?

A. Yes, I think that is correct.

Q. Could there be any reduction of animal or vegetable matter without the agency of such bacteria?

A. As I understand it there is no such reduction of consequence, except through the agency of living beings, and in the operations as a whole upon the earth, the bacteria are the principal of these living agencies, though what they do is not far different from what is accomplished by many plants belonging to the group called fungi, nor far different from the activities in this respect, of animals.

9283 I would say, though, the operations of bacteria are more commonly in graded stages, and by this I mean that the compounds are not at once reduced to their elements, but the more complex are rendered somewhat less complex, and these again still somewhat less complex, until finally the complete reduction is produced. In other words, the bacterial operation is often to a slight extent upon a very large amount of matter, while the operations of animals are generally made to take effect to a greater extent upon a small amount of organic matter.

Q. What role do bacteria perform in producing what is called oxidation of organic matter in water?

A. Oxidation itself is a chemical process, but from my information there is exceedingly little of this taking place without the aid of living organisms—

Q. Of micro-organisms?

A. Not necessarily of micro-organisms, but largely of micro-organisms. In regard to the changes taking place in water I will say that there has been a great deal of discussion upon this point. Formerly it was quite commonly understood to be the fact that oxidation proceeded as a simple chemical operation without any aid from living beings at all. All of my experience in the laboratory, entirely upon the bacteriological side and
9284 not upon the chemical side, indicates that such purely chemical operation is very slight if it takes place at all, while the oxidation of carbonaceous material due to bacteria as the agents, is very prominent; very striking.

If you will permit me, I will say that I have kept in my laboratory for years at a time, beef broth fully exposed to the air, at the temperature of the room, where everything seemed to be favorable for the oxidation of its contents if it could take place without organisms, but so long as these organisms were excluded even over great lengths of time, such reduction did not appear to take place at all.

Q. What do you infer from a bacterial examination of water from the presence of a large number of micro-organisms?

A. It seems to me, if this is natural water, that it is positive proof that there is organic matter there suitable for the food of these organisms.

Q. What kind of organic matter is it that is most suitable for the food of micro-organisms, known as saprophytes, for instance, and water bacteria?

A. Proteid matter is most suitable for many, but carbonaceous compounds are very favorable for numerous other kinds, though some of both would be needed.

9285 Q. Is this organic matter in water coming from sewers suitable for the food of this micro-organism?

A. It is evidently very suitable.

Q. Where you cannot attribute the presence of a large number of micro-organisms in water to natural causes, what inference do you draw of the possibility or probability that such contamination comes from sewage?

A. Sewage is richer food for bacteria than any other that commonly escapes into our river water courses from the land, or from the surface of the earth otherwise. There is rarely found such very large numbers of organisms in river waters except from sewage contamination, and I mean by this when the numbers run into the millions per cubic centimeter.

Q. When in the examinations of water at different points in a river, you discover a material reduction in the number of the micro-organisms found in the water, what inference do you draw with reference to the sewage that may have been in the river?

MR. JEFFRIES: I object to the question for the reason that the witness is not qualified as a sanitarian and for the further reason that he has not stated his qualifications or experience in dealing with sewage and sewage polluted waters.

9286 JUDGE SPRINGER: I think he did. He stated that he has been examining the waters for many years for state institutions for the purpose of determining their sanitary condition.

MR. JEFFRIES: He didn't state where it came from, whether it was well water or not.

JUDGE SPRINGER: He stated it came from the water supplies of the state institutions.

Q. (Question repeated)?

A. I think I am entitled to infer that the matter suitable for food for these bacteria has disappeared, and since, as has just been said, sewage is the richest food commonly in such water, I may further infer that the sewage has disappeared.

Q. Please state, Professor, whether you prepared any plates in reference to the identification of the bacillus coli-communis in the Illinois and Mississippi rivers, and the tributaries covering this period?

A. Yes, sir, I did.

9287 Q. Have you those plates with you at this time?

A. I did prepare plates, but I discover there was some error in them and I will insert them in the record at this place when I have prepared them in the proper form to correspond with the data in tables 1 to 80, of this series.

MR. JEFFRIES: That is perfectly satisfactory to the State of Missouri, or to the complainant, provided of course that if we desire after the plates have been furnished to the Commissioner by the witness, that we have an opportunity to cross-examine him with reference to the plate and the plate alone, in addition to what cross-examination we may see proper to interpose while the witness is now on the stand.

The tables, as corrected by the witness, are as follows:

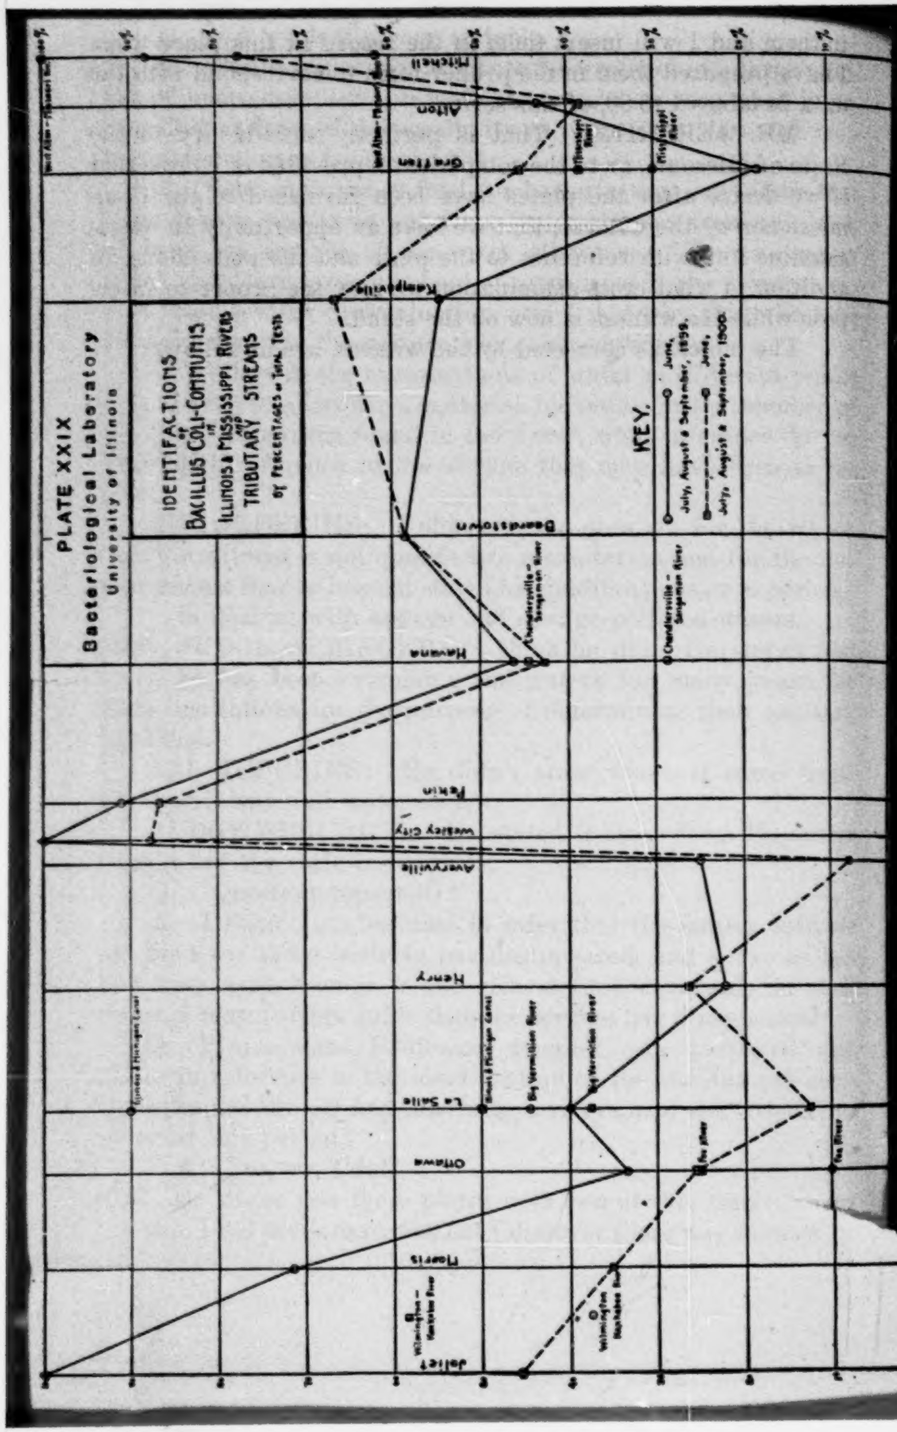

PLATE XXIX
Bacteriological Laboratory
University of Illinois

IDENTIFACTIONS OF BACILLUS COLI-COMMUNIS IN ILLINOIS & MISSISSIPPI RIVERS AND TRIBUTARY STREAMS

BY PERCENTAGES OF TOTAL TESTS

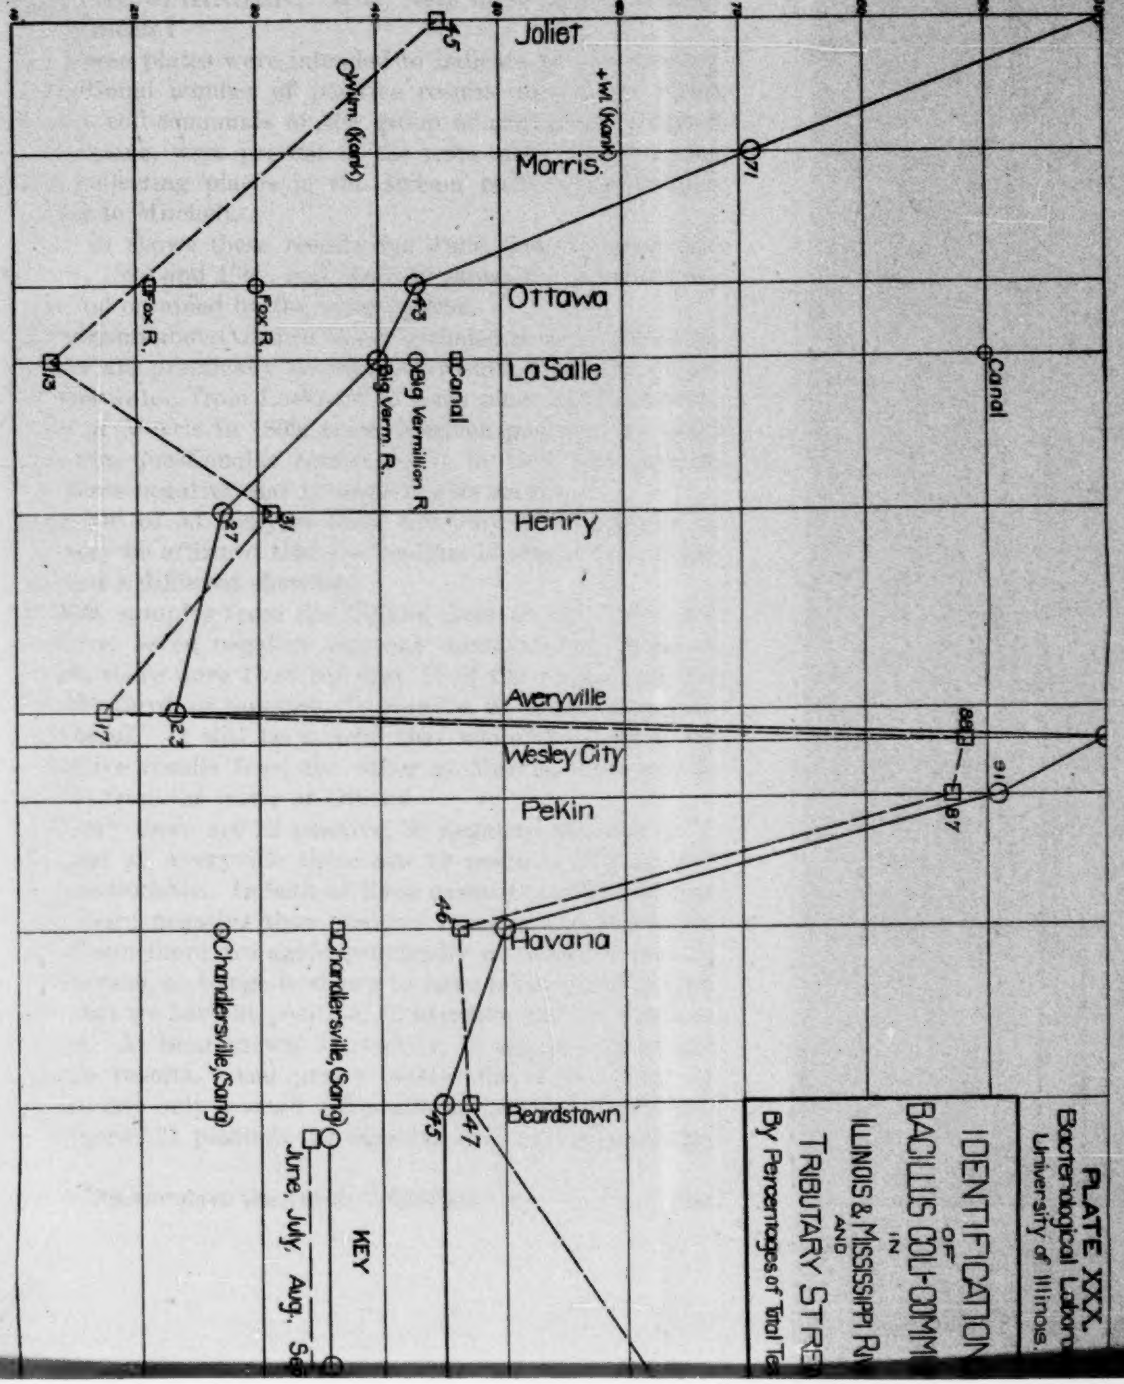

PLATE XXX.
Bacteriological Labora
University of Illinois.

By Percentages of Total Te

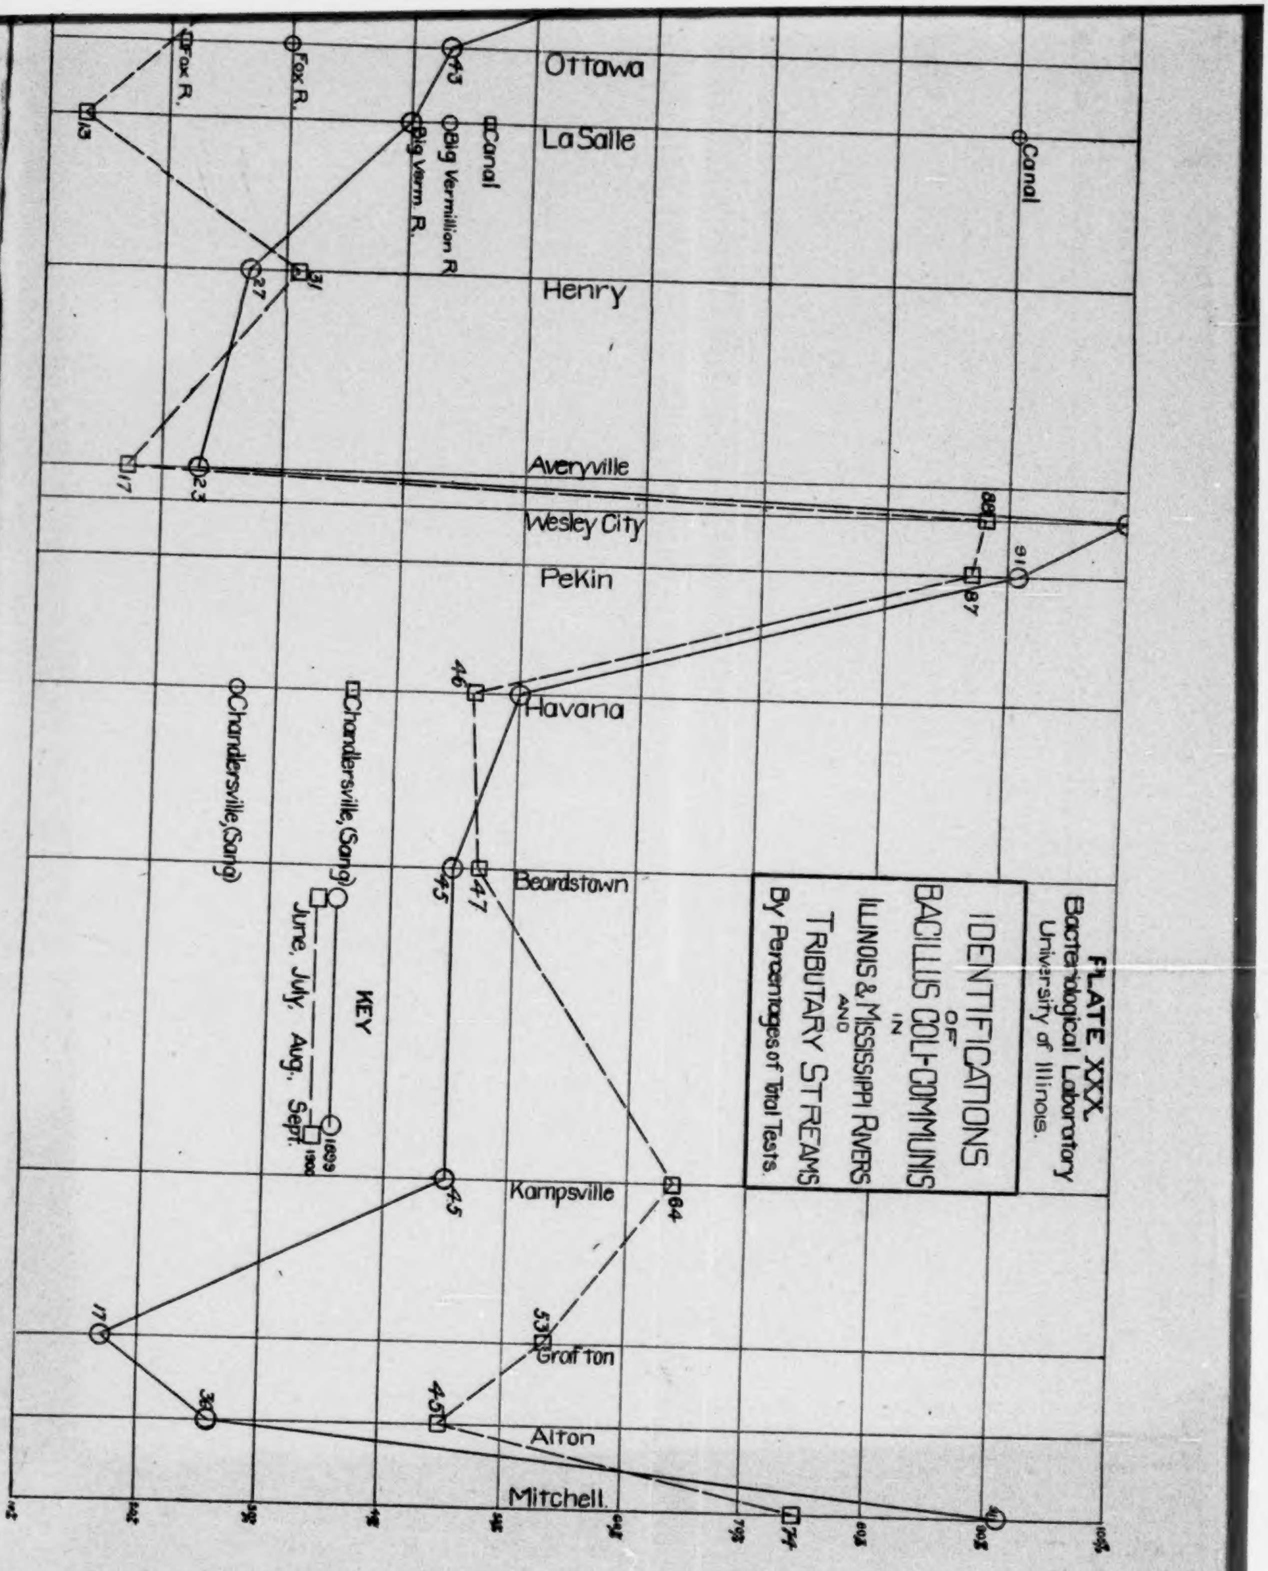

PLATE XXX.
Bacteriological Laboratory
University of Illinois.

IDENTIFICATIONS OF BACILLUS COLI-COMMUNIS IN ILLINOIS & MISSISSIPPI RIVERS AND TRIBUTARY STREAMS

By Percentages of Total Tests.

9290 JUDGE SPRINGER: What were these plates intended to indicate?

A. These plates were intended to indicate by percentages, the proportional number of positive results, that is, in which the bacillus coli-communis or the group of organisms referred to by this name, were present in the tests made by me at the different collecting places in the stream under consideration from Joliet to Mitchell.

Plate 29 shows these results for June, July, August and September, 1899 and 1900, and plate 30 shows the same for the entire period occupied by the investigation.

The stream above Ottawa is not included in this exhibit because there are practically no negative results from any of the tests in this water, from Lockport to some place above Ottawa.

Tests at Morris in 1899, show fourteen positive, no negative, and two questionable results, while in 1900 there are 23 positive, three negative and 11 questionable results.

Thus, out of 53 analyses there are only three samples in which it may be affirmed that the bacillus is absent, but at Ottawa we find a different showing:

In 1899, samples from the Illinois river at this place, ten give positive, seven negative and one doubtful test, while in 1900, there were 11 of the first, 17 of the second and five
9291 of the third, or together, 21 positive, 24 negative and six
doubtful. It will be noticed that while there were but three negative results from the water at Morris, there are 24 such results from the water at Ottawa.

At Henry there are 22 positive, 30 negative and five questionable, and at Averyville there are 19 positive, 21 negative and two questionable. In both of these cases it is observed that there are more negative than positive results; but at Wesley City and Pekin there are again practically no negative results, while at Havana, a change is shown to have taken place in such a manner that we have 31 positive, 12 negative and 14 questionable results. At Beardstown, 37 positive, 18 negative and three questionable results. And pretty closely the same thing at Kampsville, and only a small difference in the Illinois at Grafton, as follows: 31 positive, 23 negative and one questionable result.

If now we compare the results obtained from the waters at the mouth of the Illinois river, with those in a similar way from the waters of the Mississippi above the mouth of the Illinois and of the Missouri at West Alton, we shall have the following exhibit:

In the Illinois river, 31 positive, 23 negative and 9292 one questionable result. In the Mississippi river water, 35 positive, 20 negative, one questionable result; from the waters of the Missouri river 36 positive, 7 negative and seven questionable results.

This indicates that the organism is most often present in the waters of the Missouri river; next in those of the Illinois at the mouth and somewhat less frequently in those of the Mississippi, if we take into consideration the whole time of the investigation.

By reference to the graphical showing in this connection it will be seen that the less number of positive results through the whole course of the stream from Bridgeport to Mitchell was at Averyville, there being a slightly greater per centage of positive results at Grafton than at this last place. The greater number shown for the waters collected near Mitchell, seem to be due to the larger proportion or greater number in the waters of the Missouri river.

Q. Now, in the various bacterial examinations which you made of the waters indicated by you in tables 1 to 80, in those examinations, did you make any effort to determine the presence of the bacillus typhosus?

A. I did not.

9293 Q. Did you make any experiments on live animals for the purpose of testing toxins in the water?

MR. JEFFRIES: For the reasons stated by this witness that no effort was made by him to discover or determine the presence of the bacillus typhosus, in the waters of the Illinois river and the drainage canal as examined by him, I move to strike out the opinion of Professor Long, Professor Palmer and Professor Zeit, which was to the effect that they did not believe, or rather believed that the typhoid bacilli emanating from Chicago did not reach Grafton and the City of St. Louis and the intake thereof, for the reason that it has not been discovered by any of the bacteriologists who have examined samples of the water from those streams, their opinion so expressed being based upon the assumed fact that all examinations so made were with a view to determining the presence of such bacilli.

JUDGE SPRINGER: The examinations made by other witnesses have nothing to do with the examinations by this witness, and I merely desire the fact to go into the record, that he did not enter upon that branch of the case.

MR. TODD: In reply to the objection I want to suggest that no witness who has testified in this case on either side, has found the typhoid bacillus in the running waters of the
9294 Illinois river, and not only have they not found it in this
river, but there are no well authenticated cases on record, with the possible exception of six, where it has been found, and if the fact that this witness did not look for it is any reason why opinions of other witnesses should be excluded, by the application of that doctrine, it would exclude the opinion of every witness who testified in this case for complainant, as none of them found the typhoid bacillus, and the opinions of the gentlemen named in the objection were formed as much upon the testimony of Dr. Ravold, whose testimony they were familiar with, as upon the testimony of other witnesses.

MR. JEFFRIES: I am willing to admit the statement of counsel with reference to the failure to find this particular bacillus in water, and go even further with the statement that if it should be found in any water and be disseminated in the water proportionally, that the number contained in the centimeter examined, and found,—that the water would be condemned beyond question, but my motion to strike out is based on the fact that the opinion expressed by the witnesses, which was heretofore referred to, was premised upon the proposition that they believed that such bacilli did not reach Grafton or St. Louis, because they had not been found by any of the examiners who
had analyzed the water, and this witness having stated
9295 that he did not examine it for the purpose of determining
the presence of such bacilli, it affects the credibility of the opinion so expressed by the witnesses which I have referred to.

MR. TODD: I want to suggest to counsel that if he will review the testimony of Professor Long and Professor Palmer, he will find in their testimony frequently stated that they were not passing opinions as bacteriologists, but that they were strictly chemists.

JUDGE SPRINGER: Did you make any experiments on live animals for the purpose of testing toxins in the water?

A. I did not.

Q. Based upon your bacterial examinations of the waters in the Illinois river and its tributaries, and of the Mississippi river and the Missouri river to which you have referred and which are embraced in the tables and plates which have been submitted in evidence by you, what is your opinion as to the effect produced, if any, upon the waters of the Mississippi river below the mouth of the Illinois river by the opening of the Chicago drainage canal in January, 1900?

MR. JEFFRIES: I object to the question for the reason that the testimony of this witness refers to bacterial counts, without reference to the character of the bacteria, whether they be pathogenic or non-pathogenic, without reference to the 9296 pollutions of the streams of waters examined by him, or the extent of the pollution, and any opinion that the witness might give with reference to what his analyses show, would not disclose the effect of the pathogenic germs passing down the Illinois river coming from the sewage of 2,000,000 of people at Chicago in connection with the sewage from the people living upon the watershed of the Illinois river, as compared with the sewage discharged into other rivers mentioned in the question, the witness not having stated in evidence anything concerning his opinion as to the extent of the sewage pollution of any of the rivers in question, and not having differentiated in his testimony between pathogenic and non-pathogenic bacteria and the effect of the sewage disposals into a running stream, producing larger or smaller quantities of pathogenic germs, than the sewage that ordinarily comes from industrial, domestic and farm wastes.

JUDGE SPRINGER: This objection in my opinion is merely argumentative and goes to the weight of the testimony if it goes to anything, and does not affect its admissibility as the testimony of this witness, and the opinion of the witness are based upon examinations which he himself has made.

9297 MR. JEFFRIES: I submit that it goes to the admissibility of the inferences or conclusions which the witness is now requested to draw from the bacterial analyses of the waters of the Illinois river and of the other streams mentioned in the question, and the witness not having shown in evidence any knowledge of the extent of the pollution from the sewage discharges of the various cities upon the watersheds of the rivers examined by him, and not having differentiated upon the character of the pathogenic germs, the objection goes to the admissibility of the evidence called for by the question, and not to its weight or credibility.

JUDGE SPRINGER: I desire to suggest further that this witness might give his opinion upon any one of the examinations which he has made, and if the opinion is based upon that particular examination, as to what that examination means, and he may give it as to all of them at once.

MR. TODD: I move to strike out all of counsel's statements except so much of it as is a legal objection to the question.

Q. (Question repeated.)

A. In my opinion the very decided reduction of the number of the bacteria found in the course of the stream up to the time the waters reached Averyville, causing the waters at this place to assume the character of a normal river water, indi-
9298 cates that the contaminations from the sewage introduced into the stream from Chicago have disappeared at this point, and I cannot otherwise than conclude that the evidence now presented shows that the water at the mouth of the Illinois river at Grafton is practically free from any such contaminations introduced at Chicago.

I find also that the contamination as indicated in the water at the inlet tower at the chain of rocks, has a larger portion of its contamination from the water of the Missouri river rather than from the combined waters of the Illinois and the Mississippi at this point. I can say that the opening of the drainage canal has had no effect upon the waters of the Mississippi river one way or the other.

JUDGE SPRINGER: Professor, did you make any bacterial examinations of the waters of the Illinois river, the Mississippi river and the Missouri river in the months of October, November and December, 1901?

A. I did.

Q. Under what circumstances were those samples taken?

A. They were taken in the same manner and by the same

B. Coli-Com. 57.1 per cent.

9319 JUDGE SPRINGER: State whether you computed any averages in reference to these tables, and if so, what these averages show?

A. The averages were computed from the total tests made from the waters collected at each place; and also the percentage of positive results from all tests made for Bacillus coli-communis, were made from the waters in each place.

Q. Now what do those show in each of the tables?

A. The average number of bacteria shown for Averyville in this examination from October 16th, to December 30th, is 13,691 and the percentage of positive tests for the Bacillus coli-communis is 6.2.

The average number of bacteria from the Illinois river at Pekin for the time mentioned, is 299,000; and the percentage of positive tests for the Bacillus coli-communis, is 76.

The average number of bacteria from the Illinois river at Grafton is 8,441, and the percentage of positive results for the tests for the coli-communis at this place, is 10.7.

Of the waters of the Mississippi river above the mouth of the Illinois at Grafton, the average number is 5,407, and
9320 the percentage of positive results in the tests for Bacillus coli-communis is 11.5.

I may state there were four places of collection from the chain of rocks in a cross-section of the river. Those taken from near the Illinois shore averaged 52,177, and the positive results for the Bacillus coli-communis tests was 21.7 per cent.

Those taken from mid-stream averaged 43,185, and the positive results for the tests for Bacillus coli-communis, is 50 per cent.

Those taken near the intake tower, the average number was 127,862, and the number of positive tests for Bacillus coli-communis is 36.3.

The average number of bacteria from the water taken near the Missouri shore amounted to 32,845, and the positive results of the tests for bacillus coli-communis shows 57 per cent of the total number of tests.

Now the general average for all tests at this point was 63,402 bacteria per cubic centimeter, and the positive tests for bacillus coli-communis is 41.1 per cent.

From the waters of the Missouri river at Fort Bellefontaine

the average number of bacteria was 127,353, and the
9321 positive results for tests for Bacillus coli-communis is 57.1 per cent.

ADJOURNED until 10:00 A. M. Friday, November 27th, 1903.

10:00 A. M., Friday, November 27th, 1903.

9322 Present, the Commissioner and same counsel representing the respective parties.

Continuation pursuant to adjournment.

PROF. T. J. BURRILL,

resumed the stand for further direct-examination by Judge Springer, and testified as follows:

Q. Professor, at the time of adjournment day before yesterday, you had put in evidence certain tables showing colony counts and the presence of bacillus coli communis as found in samples of water taken from the Illinois, Mississippi and Missouri rivers, in 1901. Please state whether you have made a table of averages graphically indicated, based upon these tables of ascertainment?

A. I have.

Q. Will you please present it?

A. (Witness produces plate).

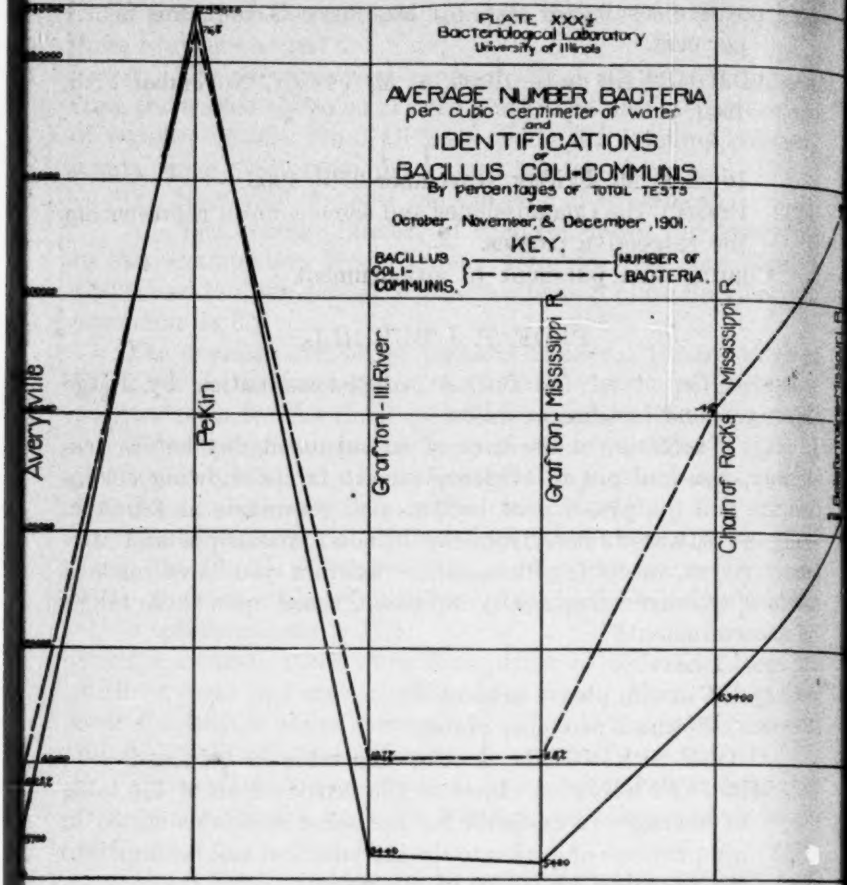
JUDGE SPRINGER: I offer this table in evidence.

MR. JEFFRIES: I object to the introduction of the table of averages in evidence for the same reason as stated in
9323 my previous objection to the introduction and reading into the record of all tables of averages.

JUDGE SPRINGER: This table of averages to be known as plate No. XXX½ of this series.

THE WITNESS: The table is as follows:

9324



Q. Now please state professor, what significance you at-
9325 tach to the colony counts and the presence of the Bacillus coli communis as they appear in the tables which you put in evidence, and also as graphically illustrated by the plate just put in evidence?

A. This series of investigations shows very closely just what was presented in the series for 1899 and 1900, already presented, and gives clear evidence that the water from the stream of Averyville is comparatively pure, or at least free from great numbers of micro-organisms, and also quite commonly free from the bacillus coli communis. The percentages of total tests which were positive in this examination proved to be 6.2

Q. That 6.2 per cent refers to the percentage of times that you found the Bacillus coli communis?

A. Yes sir. If we compare this with the water taken from the Pekin station, we find a very great difference, and it shows local contamination, since there are an average of 299,000 bacteria to the cubic centimeter, and 7.6 per cent of positive tests for the Bacillus coli communis.

This pollution at Pekin seems to have disappeared at the
9326 mouth of the Illinois river at Grafton, since the average
number of colonies is 8,441, and the percentage of positive tests for Bacillus coli communis is 10.7.

If we compare the results from the waters of the Illinois river near its mouth, with that of the Mississippi river above the mouth of the Illinois, we find the result in regard to the number of colony counts slightly in favor of the Mississippi river as was found in the previous case, the average here being 5,407. This difference between 5,407 and 8,441, may or may not show a constant condition of things, as the difference is too small for this purpose, but the tests in regard to these two waters made for the determination of Bacillus coli communis, favor somewhat the Illinois river water as against the Mississippi river water, since the percentage in the former is 10.7 and in the latter 11.5.

At the chain of rocks, where four samples were each time taken across the stream, the indications are that the pollution increases from the Illinois shore to the Missouri shore, as this series of counts show, namely, for the Illinois shore 52,177, for the midstream, 43,185; for the intake tower 127,862 and for the
Missouri shore 32,845. This last is the only count which
9327 does not support the statement just made.

For the determination of Bacillus coli communis in the same water we find beginning with the sample taken near the Illinois shore, 21.7 per cent; from midstream 50 per cent; from the intake tower 36.3 per cent; and from the Missouri shore 57 per cent.

Comparing now these last results with those obtained from the waters of the Missouri River at Bellefontaine, or as it is sometimes called, West Alton, the indications are that this latter stream is considerably more contaminated, since the average number of bacteria per cubic centimeter is 127,353, and the percentage of positive tests for Bacillus coli communis is 57.1.

This means, so far as this evidence can be taken to mean anything, that the waters at the intake tower are largely derived from those of the Missouri river, and to present this a little more clearly, the results of the examinations of the water from the Missouri at Bellefontaine and of those at the intake tower may be placed together. From the former, that is the Missouri, the average number of bacteria per cubic centimeter is 127,353; at the intake tower the average is 127,862. The percentage of positive tests for Bacillus Coli Communis from the Missouri river is 57.1 per cent, and the intake tower 36. 3 per cent.

9328 The whole examination seems to indicate that the water which is comparatively pure at Averyville, becomes very greatly contaminated at Pekin, clears up again at Grafton, and at this point compares favorably with the waters of the Mississippi river above the mouth of the Illinois, and very favorably with those of the Missouri at Bellefontaine.

Q. What significance do you attach in running river water, to the presence of Bacillus coli communis?

A. The presence of this organism means to me more than anything else, that the water is contaminated with sewage, and that this shows its bad quality for drinking purposes.

I will say that since Bacillus coli communis, and Bacillus typhosus is mainly derived so far as they are found at all in water, from the same source, that the very common presence of the former may be held to give some indication, though by no means a positive proof, of the presence of the latter.

Q. Did you have any difficulty in determining the presence of the Bacillus coli-communis in your examinations of the water?

A. I cannot say that we did.

Q. Professor, on day before yesterday, in your testimony in this case, you gave it as your opinion that the sewage from the City of Chicago had not produced any effect either

9329 one way or the other, in the waters of the Mississippi river, covering the months of October, November and December, 1901. Please state whether you still entertain that opinion after taking into consideration the tables which you have given in evidence this morning?

A. I don't think there is anything shown by these later examinations to warrant any change in that opinion.

CROSS-EXAMINATION,

By Mr. Jeffries.

Q. Professor, you have been studying bacteriology practically ever since there was anything known of the science of bacteriology, have you not?

A. This is the case in reference to the subject of studies that were made in America, or in this country, and to a considerable degree as known anywhere.

Q. Now before you commenced the study of bacteriology what was your line of work?

A. Cryptogamic botany, as a general specially was my line of investigation. I had a wider subject for teaching.

Q. Had you studied biology prior to that time?

A. 1877?

Q. Yes?

A. Why, yes sir.

9330 Q. Was it in connection with biology or botany that you commenced the study of bacteriology?

A. Please let me say that I have been accustomed to use the term "botany" as a branch of biology.

Q. Then what was the character of your work during this time in which you used botany as a branch of biology, and to what character of work and limits did your investigations carry you?

A. Well, the part of my work that had a more special bearing upon the subject now included under the term of bacteriology, was that upon microscopic fungi, especially those kinds of these low organisms which produce diseases in plants. To a less extent for the purposes of comparison of any of the lower forms of plant life included under the general term "fungi."

Q. Now you made bacteriological investigations in connection with agricultural and horticultural experiments?

A. Yes sir. My first studies upon bacteria in the sense of following the course of development of any species were upon the disease of pigs known as cholera, or hog cholera, but this only served as an introduction to the more serious studies, those of much greater extent, upon somewhat similar organisms producing disease in plants, and I may be permitted to state that I worked out and published the first disease known to be 9331 produced by any kind of bacteria on any living plant.

Q. What was that?

A. This was the disease called blight in pear and apple trees,—fire-blight, sometimes.

Q. Now in your study with reference to the disease known as hog cholera, state whether or not it was your purpose to discover if possible any connection between the disease itself, and the food that was used or consumed by the animal?

A. Only in an incidental way. It was mainly my purpose to try to find out whether or not the bacteria found in the diseased tissues of animals were really the cause of the malady or not.

Q. And you made no investigation with the view of determining whether or not those same bacteria were found in the vegetable matter that was used by the animal as food?

A. No sir, except I did endeavor to find out how the suspected organisms entered the body of the animal, whether in the food or through wounds through the skin.

Q. Or by breathing it from the air?

A. Yes, that would be the third method of posisble entrance. Perhaps I should explain further that these studies were made in connection with the first Commissioner appointed 9332 by the United States Department of Agriculture to investigate this disease, and were made for a great part in my laboratory at Urbana, and my studies were largely in connection with his work. That was Dr. H. J. Detmers, now of Columbus, Ohio.

Q. Doctor, has the greater part of your work been along the lines of the diseases of animals or those of human beings so far as your bacteriological examinations have gone?

A. I really never made any serious studies of the bacteriological diseases of human beings, except in the studies of the organisms, themselves. The studies directly upon the living beings which I have made, have been almost altogether from the standpoint of the bacteria, for the purpose of gaining information in regard to their life history and mode of development, and not to any considerable extent from the pathological standpoint.

Q. You have not then studied bacteria particularly with reference to the cause of the disease, but with reference to its life history when you know that a certain bacteria does produce disease?

A. That is the general statement. In a few cases in the diseases of human beings, I have undertaken to find the cause in the discovery of the particular organism to which the
9333 disease might be attributed and to prove that the suspected organism was the cause of the disease.

Q. Have you ever made any experiments for the purpose of differentiating between the effect of the bacteria which comes from human excreta, and those which come from ordinary domestic animal excreta?

A. I have not.

Q. Have you ever made any investigations with reference to differentiating between the effect upon the human system when taken into the system, of bacteria which come from human excreta, and the bacteria which come from the decomposition of vegetable matter?

A. I have not usually made such studies. The main exception to this has been in cases of the suspected presence of Bacillus typhosus.

Q. Those examinations were with particular reference to the effect of the Bacillus typhous, and its source, were they not?

A. They were for the main purpose of determining whether or not a water having a few of the individuals of Bacillus typhosus, or which was suspected to have some individuals of this species, were more deterimental to health than those containing a large number of other organisms, or in other words, to
9334 determine what report should be made upon the results

of an examination of water as to its liability to produce serious diseases.

Q. Now then, aside from the typhoid bacilli, what other disease producing bacteria have you studied?

A. You mean now, human diseases?

Q. Human diseases?

A. The bacillus tuberculosis, and upon this I may state that as soon as the discovery of this organism was made, I devoted very considerable attention to it and as one result found a possibility of detecting the organism through a special stain that has been pretty widely known.

I also at a later time made a considerable study upon the disease commonly called grip. These results were never published.

Q. You made no investigations with reference to any other diseases commonly known as water borne diseases, than the typhoid?

A. I think I may say I have not.

Q. What was the character, professor, of the water supplies of the various institutions which you stated you examined on behalf of the various state institutions?

A. They were almost in every case of local supply, and 9335 mostly from wells.

Q. Did you during that time examine any water from wells that was known to be infected with typhoid?

A. Not that was known to be infected, but was seriously suspected of being infected.

Q. Did you ever find the Bacillus typhosus?

A. In such waters?

Q. Yes?

A. No sir.

Q. Did you find the colon?

A. Yes.

Q. And as you found the colon and from the finding of the colon you reasoned as to the presence or non-presence of the typhoid?

A. So far as I thought it permissible to do so yes.

Q. Now in forming an opinion as to the presence of the typhoid in the waters of those wells from the fact that the analyses show colon, you took into consideration did you not, the physical surroundings and general sanitary conditions of those physical surroundings?

A. An endeavor was always made to do so.

Q. In any instance did you find large quantities of water bacteria?

9336 A. Yes sir.

Q. And of other kinds of bacteria?

A. Such as bacillus coli communis that is frequently found in water, though not commonly classed as water bacteria.

Q. Is there any difference, professor, between the ordinary water bacteria and that bacteria which is produced by decayed animal matter?

A. There is no sharp differentiation between the two groups, though there are certain differences which in detail can usually be pointed out.

Q. Do you know the effect of oxidation upon ordinary water bacteria?

A. Some of the ordinary water bacteria can thrive only in the presence of free oxygen. Others of them can best develop where there is little or no free oxygen, and there are still others occupying an intermediate relation in this respect.

Q. Do you know what effect oxidation has upon the colon?

A. It can live pretty nearly equally well in the presence or absence of free oxygen, provided other conditions are proper for it.

Q. Do you know the effect of oxidation upon the typhoid bacilli?

A. They also can live under both of these conditions.

9337 Q. I will ask you if it is not a fact that larger quantities of bacteria of all kinds are generally found in compositions containing small amounts comparatively speaking, of oxygen?

A. This is commonly true with reference to water.

Q. Is it not a fact that in highly polluted water, the ordinary bacteria at work in that water, have a tendency to overgrow certain kinds of parasitic bacteria which may be contained therein?

A. I believe that to be very generally the case.

Q. And when we say overgrow, we do not mean a disappearance of the parasite, but that greater numbers of the ordinary bacteria have been produced until we become unable to differentiate or to distinguish the parasite?

A. The latter is very thoroughly known to be true; that the ordinary species multiply to such an enormous extent as to make it very difficult to find any other given species, which does not multiply, or does not multiply much. It is also, however, very commonly believed, that the excessive multiplication of those kinds found in great numbers in water, actually tend to kill out those not adapted to the conditions found in the water, as is the case of most parasitic organisms.

Q. Have you ever made any determinations with reference to the life or longevity of the disease producing bacteria?

9338 A. In very numerous instances, such tests have been made in my laboratory, partly by myself and partly by my students under my direction, but probably in no case under such conditions as will be taken certainly to throw light upon their life under their usual circumstances.

Q. As contained in a water supply?

A. As contained in a water supply. My examinations for that purpose have been in closed receptacles.

Q. Is it not a fact professor, that there is nothing in the science of bacteriology which will disclose the exact longevity of pathogenic bacteria in the waters of a lake or river, or of any water supply into which they have been discharged? In other words, has the science of bacteriology been able to produce artificial conditions as would exist in the water itself so as to enable a correct determination of the longevity of the disease producing germs?

A. I must say that so far as I know, all of the tests of which published accounts have been made, are open to criticism when we come to consider the conditions under which these artificial tests were made, and the conditions actually existing in nature.

Q. Do not bacteriologists reason from bacteriological analogy, that pathogenic or disease producing bacteria live
9339 longer in the water while in the running stream than in

the laboratory experiments, for the reason that conditions are more favorable in the river than in the laboratory, in that the bacteria as contained in the laboratory tests are prisoners and to a large extent, are unable to care for themselves as they are while contained in the running water, being living organisms?

A. I cannot say that this is commonly the case. Of course the conditions artificially produced in a laboratory are not only very different in themselves, and are subject to great variations, but they are very different also from those in ordinary running streams; but if I can answer the question in a general way, I think the preponderance of opinion would be that pathogenic bacteria in the open running streams have less advantage than they commonly have in a bacteriological laboratory test.

Q. But as to the exactness of that opinion, what would you say?

A. I cannot say that it is an actual fact.

Q. Professor, do you know whether or not the pathogenic bacteria or any kinds of them are dependent organisms while contained in a polluted water; that is to say, do they depend upon other organisms or material as a food supply for
9340 their existence?

A. There is a great difference in this respect in regard to different kinds.

Q. That is, you mean difference in opinion?

A. No sir, different kinds of species of organisms. Some of the disease producing bacteria are plainly in their main activity, saprophytic, or such as commonly live upon dead organic matter outside of the body, while there are others that are entirely incapable of getting their food supply except from the living tissues, though they may live for a considerable length of time outside of the host, as the subject is called, preyed upon by these organisms.

Q. Now do you know what kind of pathogenic or disease producing bacteria are generally known as saprophytic also?

A. The bacillus of tetanus, producing the disease commonly called lock-jaw is one such. It passes its life for the most part, and multiplies its kind to a very great extent in ordinary garden soil, and can do so perpetually, without at any time in the life of the individual, or of the species being an inhabitant of the living animal, but when once introduced into the tissues it is a virulent, disease producing organism.

Q. Does that particular bacillus known as the bacillus tetanus feed upon other organisms in water, or is there
9341 anything in bacteriology that will disclose that?

A. No species of bacteria feed directly upon other bacteria. No bacteria of any kind are capable of taking into their substance any solid particles, and since however small they may be, all bacteria are solid bodies, it is impossible that the other bacteria should actually feed upon them. They may feed upon the dissolved substance of other bacteria.

Q. But as to whether they do or not—

A. Oh yes. I think that is positively assured, that they do.

Q. Do they propagate?

A. Very largely.

Q. In the water of a running stream?

A. Certain kinds certainly do.

Q. Of pathogenic bacteria?

A. Usually not. I cannot say that there are no pathogenic bacteria which do not propogate in streams.

Q. As a general proposition is it not true that they will not propogate unless the proper temperature has been obtained?

A. There is a great difference in different species of bacteria in this regard.

Q. Yes, but I mean professor, proper temperature has been obtained with reference to each particular class or
9342 kind or species of bacteria?

A. That is true as a general law, though some species are very much more limited in regard to the range of temperature than others, for some can only live and propogate within a few degrees of a certain temperature, while others may have considerable range over a greater number of degrees, but the temperature must come within that range in order that they may grow.

Q. Do the colon bacilli multiply in a running stream?

A. Yes.

Q. At any temperature?

A. No sir. Under favorable conditions.

Q. At what temperature?

A. They multiply freely at the temperature of 20 degrees centigrade up to 41 degrees centigrade.

Q. In Fahrenheit that would be?

A. That would be about 68 to 100, and more. They will multiply to some extent at a lower temperature.

Q. Do they multiply rapidly at the proper temperature?

A. Very rapidly; the growth is very—the multiplication is pretty rapid.

Q. Do they multiply in sterilized water?

A. Yes sir.

Q. At the proper temperature?

9343 A. If other things are favorable.

Q. Will ordinary water bacteria multiply in sterilized water?

A. Yes.

Q. Will the typhoid bacilli multiply in sterilized water at proper temperature?

A. It will if the proper food supply is present.

Q. In other words, if the water is sterilized, then a certain food supply must be introduced with the typhoid bacilli?

A. I may say that I did not understand the reference to sterilized water to preclude its having certain food matters in it for bacteria.

Q. Of a soluble character?

A. Of a soluble character, and so sterilized water may be very fit indeed for the development of bacillus typhosus.

Q. Then professor, a glass of water that is perfectly transparent and clear, colorless and odorless, containing a typhoid bacillus, if raised to a certain temperature, would cause a multiplication of that typhoid bacillus provided it contained the soluble food supply?

A. Yes sir.

Q. Yet a bacterial analysis of the entire glass of water before it was raised to the proper temperature, would disclose only the one bacterium if a bacterial analyses be made accurately? 9344

A. And sufficiently extensive that would be the case.

Q. And the water might be analyzed bacterially and the typhoid bacilli not found?

A. Very easily.

Q. It is more easily believed that it would not be found than to believe that it would be found?

A. That is certainly the case.

Q. Then a bacterial analysis of water does not speak with exactness as to the total number of micro-organisms or bacteria contained in the water?

A. It never can be true that the exact number in any considerable volume of water can be revealed by a bacterial analysis.

Q. There would be more reason to believe that pathogenic bacteria would multiply in a water containing the soluble substances that were produced from the solid particles of pollution, than from those solids themselves, if raised to the proper temperature?

A. I think that would be commonly true. It is certainly true that there must be at least a certain proportion of water in connection with the solid material in order that the
9345 development of bacteria shall take place at all.

Q. What waters are more likely to contain the typhoid bacilli?

A. Those waters that have been recently infected through the medium of excretions from the human body.

Q. Assuming that water has been infected with the typhoid bacilli at a given point, is it within the science of bacteriology to determine the exact point in the river where the water would not be affected by the typhoid bacilli so deposited?

A. If sufficient attention is given to the word "exactness" in the question, I will say it is impossible so to determine.

Q. Professor, have you ever made any examinations with reference to the determination of the proportionate quantity or numbers of the colon bacilli that come from human beings, and those which come from animals?

A. I cannot say that I have, but I have determined that they are very large in the daily evacuation of both man and the higher animals.

Q. Is there any difference in the construction, nature and characteristics of the colon bacilli that come from the intestines of the human being and those that come from the intestines of the lower animals?

9346 A. The colon bacillus seems to be peculiarly subject to some variation. This is true to such an extent that there has been much discussion as to whether the individuals referred to by this name are really members of one species or group of allied species. Now then, there seems to be something of a similar variation in regard to the source of the particular individuals referred to under this name. Sometimes those from a human being have been found to have certain minor variations from those derived from other animals, but I cannot say that there is any clear distinction which can be made or referred to between the races of these organisms in consequence of such difference of origin.

Q. Is it not a fact that those that come from the human intestines live longer than those that come from the domestic animal?

A. This is often asserted to be true, and it probably is true, especially with reference to those which come from herbivorous animals.

Q. Is the distinction or difference between the two such as is recognized by bacteriologists in the examinations of water for sanitary purposes?

A. No sir.

9347 Q. Professor, in your analyses of the water supply of the various institutions to which you have testified, did your opinion as to the sanitary condition of that water depend upon the number of counts or the character of the bacteria that you found in that water?

A. Upon both, but more especially upon the latter, the character of the bacteria, and in this case almost exclusively upon the presence or absence of the Bacillus coli-communis.

Q. When you say this case, you mean the opinion you expressed in the present case?

A. No. I mean in relation to the character of the organism.

Q. Now did you consider the physicial surroundings as well as the sources of pollution?

A. I rarely visited the locality. The opinion given in this case was from correspondence, though an endeavor was made to find out as much as possible of the surrounding conditions and any history that could be given connected with the case in any respect.

Q. Now any knowledge of those conditions that was obtained by you, did you consider such knowledge in forming your opinion?

A. Yes sir.

9348 Q. Is it not necessary, professor, to know the physical conditions with reference to the character of the discharges or deposits in the river, in order to determine the sanitary condition of that water from a bacteriological standpoint?

A. It is certainly true that the interpretation to be made from the bacteriological examinations must be influenced by the knowledge of the physical conditions and all other matter pertaining to the sources of pollution.

Q. In your opinion as to the sanitary condition of the water of the three rivers, the Illinois, the Mississippi and the Missouri, did you take into consideration the extent and the sources of pollution and infection?

A. Not to any very considerable extent, from my own personal investigations, but if reference is made to such knowledge as could be derived from investigations of others, I did take into consideration such sources.

Q. Then your opinion is based in part upon what others have told you with reference to the physical conditions of the three rivers?

A. Yes, I never made any personal examinations as to the quantities of polluted matter which entered the river. I have been in a position to observe in a general way the main pollutions entering the Illinois stream, but not in regard to the Missouri river.

9349 Q. You do not know of your own knowledge, whether the polluted and infected material deposited in the Mississipi river above Grafton is greater or less than deposited into the Illinois river above Grafton?

A. Yes, I think I do know.

Q. Of your own knowledge?

A. Of my own knowledge.

Q. Is it more or less?

A. *That the bulk of the pollutions of the Illinois stream* is greater.

Q. How is it with reference to the Missouri river?

A. I have never had from my own knowledge any opinion in regard to the pollution of the Missouri river, and such general knowledge as I have of the stream I have continually been surprised at my results of the examinations of the water taken at Fort Bellefontaine; surprised that the evidence existed of so great contamination somewhere above that point.

Q. And that was because of the fact that you knew that the sources of sewage pollution were not great, or as great as those upon the Mississippi and Illinois?

A. That the sources of pollution did not seem to be anything like as great as they were at the specially polluted
9350 points of the Illinois stream. Of course I know in a
general way that the Missouri river is previously contaminated from the sewage of St. Joe, Atchison, Kansas City, Kansas, and Kansas City, Missouri, but I have no special information of very great contamination of that stream in its lower courses.

Q. You have no particular information with reference to the number of people residing upon the Missouri and Mississippi river watersheds as compared with those upon the watershed of the Illinois river including the city of Chicago?

A. I am well aware that the population on the watershed of the Illinois including the city of Chicago is very much greater than that affecting the Mississippi above the Illinois and that of the Missouri above its mouth.

Q. You never made any analyses of the Illinois river except those you have introduced here in evidence?

A. Yes sir.

Q. That is an occasional analysis?

A. Yes sir.

Q. But no series of analyses?

A. No sir.

Q. Is there anything, professor, in the science of chemistry that will disclose the effect of saprophytic bacteria upon typhoid bacteria or bacilli?

9351 A. I should be unable to answer very effectively, since I am no chemist. I should suppose not.

Q. But as a bacteriologist I mean.

A. I should suppose not.

Q. In other words, bacteriology does not disclose what effect the presence of the saprophytic bacteria have upon the life or longevity of the typhoid bacillus?

A. You mean now the chemical effect?

Q. No, I mean what effect have they upon them with reference to their disappearance and removal and the elimination of the one or the other from the sewage?

A. I think there is a considerable amount of knowledge on that subject.

Q. Decreasing quantities of saprophytes means increasing opportunity for the longevity of typhoid in water, doesn't it?

A. That is possibly true, but the decreasing numbers of saprophytes is altogether a different matter from the small number of saprophytes originally present. In this latter case there is no doubt but that the Bacillus typhosus other things being equal, has a better chance for survival.

Q. I believe you stated that there was nothing in bacteriology that would disclose the fact that the typhoid bacillus was dependent upon other bacteria, or lived independent

9352 of them in running streams.

A. I do not remember to have so stated.

Q. The temperature not being sufficient to produce a multiplication of the typhoid?

A. I think the evidence is quite conclusive that Bacillus typhosus in ordinary running streams in our country does not multiply very largely, and one of the reasons for this is, the want of a sufficiently high temperature.

Q. In making determinations for the colon bacillus, does a bacteriologist undertake to determine the number of counts of colon, or simply the presence of colon in water for sanitary purposes?

A. Both are undertaken at times, or either result may be prominent in the mind of the investigator in a given case or even commonly. I think ordinarily some attention is given to both of these matters.

Q. Is it not a fact professor, that it is almost impractical to determine the counts of the colon as contained in water?

A. That depends upon the amount or number of the organisms present, belonging to this species. If they are somewhat rare in the water, then it can be approximately determined how many there are in a given quantity of that water.

9353 Q. Do you mean by that, that it depends upon the number of other bacteria present?

A. No sir, I mean if the analyst supposes the organism is in no great numbers in a given water under examination, he may try measurements of the water in such a way as to determine how many of the organisms exist in any certain measure. For instance, he may adopt a method of examining carefully a cubic centimeter of water divided into tenths, and find out in making these tenths any of the organisms existing. If on an average for such tests he finds that five of the divisions of the cubic centimeter, yield positive results and five do not, he concludes that there are at least five of these organisms in that cubic centimeter. The fact that half of the results showed no presence of the organisms, is taken to mean that in that proportion the organisms are absent from certain quantities of water.

Q. But in that method it cannot be accurately determined because the presence of colon in one of the tenths might be shown from the gas that is produced by two or more bacilli?

A. There certainly may be present two or more of these organisms, without the power of the investigator to discover it. 9354

Now, professor, in this connection please explain what bacteriologists mean by masking, and state whether or not the colon is not to a large extent and in a number of instances, masked?

A. That is a term which usually refers to the comparatively larger numbers of other organisms present in a given sample of water, and when these other organisms are of a similar character to the one under special examination, it makes it very difficult to discover the latter.

Q. Now is that true with reference to the colon?

A. Yes, but not by any means so true as in regard to some other organisms, since the colon commonly multiplies.

Q. It is particularly true with reference to the typhoid?

A. Yes it is particularly true with reference to Bacillus typhosus.

Q. Now is it not a fact that the presence of the colon bacillus is more readily detected in water than the typhoid, not only because of its presence in greater numbers, but because of the fact that it produces a certain gaseous substance in the experiment from which the determination is obtained, while the typhoid bacillus does not produce a gas?

A. It is a fact that the production of gas by the colon
9355 bacillus serves as a very critical test of its presence, while
the non-production of gas in the medium gives no indication as to whether or not the Bacillus typhosus is present or absent, because Bacillus typhosus does not produce gas.

Q. Now these determinations of the presence of the colon bacilli are made from the presence or absence of gas in the test?

A. That is one of the tests of about a half a dozen.

Q. Hasn't this test been adopted by bacteriologists as the most perfect of all tests?

A. I think it is true that most bacteriologists consider this the most critical test in the separation of this organism from most others likely to be met with in the analysis of water, though not with respect to certain other organisms.

Q. This is the test which you have employed in your determinations, the results of which you have read in evidence in this case?

A. We have always employed this test but have not neglected other tests also.

Q. But professor, in the determinations which you read
in evidence, those determinations were made by this test,
9356 this gas test which we are speaking of?

A. Not exclusively. I regard the action of the colon bacillus upon milk quite as important in the differentiation of these from other organisms, as the test for gas.

Q. Is there any other organism that will have the same effect upon milk as colon?

A. Yes, very closely the same.

Q. What is it?

A. There is the lactus aerogenes, which has an exceedingly similar effect, except that it is slow in action.

Q. Is that the only one that has the same effect?

A. No sir, there are others also. There are small differences in probably all cases. The Bacillus coli-communis cannot be readily differentiated from all other organisms by any one test or I think, by any two tests.

Q. There are other organisms that produce gas?

A. There are.

Q. But with corresponding percentages?

A. Somewhat closely the same as that of Bacillus coli-communis, but if the number of tests are extended, the production of gas in connection with these other tests becomes a very critical test of the Bacillus coli-communis, or the presence of coli communis.

9357 Q. Now professor, in making a test for the discovery of colon in water, the fact that the test or the examination fails to disclose its presence, does that prove conclusively that it is not present?

A. By no means, since the quantity of water examined by a bacteriologist is small compared with the total volume, and possibly in some cases when, owing to the peculiarities of the life history of the special organism it does not respond to the test applied for it.

Q. Although it may be present?

A. It possibly may be present and its presence not made manifest owing to special effects of development of this particular organism or race.

ADJOURNED until 3:45 P. M., same day, Friday, November 27th, 1903.

9358 3:45 P. M., Friday, November 27th, 1903. Continuation pursuant to adjournment. Present, the Commissioner and same counsel representing the respective parties.

PROF. T. J. BURRILL,

resumed the stand for further cross-examination by Mr. Jeffries and testified as follows:

MR. TODD: Professor, there is one question that was omitted in the direct-examination, that I desire to call your attention to before concluding your cross, with the permission of counsel, and that is this:

Have you made any observations or experiments in regard to the life of the bacillus prodigiosus in water, and if so, please state the results of those observations and your opinion as to the longevity of that bacillus in water?

A. I have made such examinations frequently. This bacillus is well known to all bacteriologists, and is made common use of in bacteriological laboratories for various purposes. In my own work, it has been frequently used in connection with other organisms in various kinds of water contaminated 9359 and otherwise, and the general result has been that this organism soon dies out in any kind of water.

I happen to have the exact results of an experiment made this last summer, and found that when the Bacillus prodigiosus was placed in water entirely sterilized and free from other organisms and kept at about room temperature, though the room temperature at that time varied between 20 and 25 degrees Centigrade, the organism did not last over four days in a living condition. When put in with various other organisms some of which could live continuously in water, it was found that in several instances the bacillus died after a period of three days. In one instance a few of the organisms were found after a period of five days, but in no other case were there any found living up to that length of time.

I think I am entitled to the opinion that under any ordinary circumstance, Bacillus prodigiosus will not live in ordinary tap water or in common river water or in sewage polluted water more than five days.

CROSS-EXAMINATION,

Resumed by Mr. Jeffries.

Q. Professor, from your bacterial analyses of the water of the Illinois river at any point or at any of the points in question, taking into consideration what you know of the 9360 source of the pollution, do you consider the water suitable for domestic and drinking purposes in the condition that you found it at the time of the analysis?

A. I should not consider it proper water to drink.

Q. Did you make bacterial analyses of the water of Lake Michigan at any time?

A. Yes, continuously during the period of investigation from June, 1899 to October, 1900, as taken from a tap in the municipal laboratory at the City building.

Q. Did you make any for 1901?

A. No sir.

Q. Is the data with reference to those analyses contained in any of the tables which you have introduced in evidence?

A. I believe not.

Q. Have you the analyses or data with you which show those determinations?

A. Yes sir.

Q. I will ask you if you know what particular crib this water was drawn from that you analyzed?

A. No sir, I do not.

Q. I will ask you if it was the same water or a representative of the same water that was analyzed chemically by Professor Palmer?

A. It was from the same samples.

9361 Q. I will ask you if it is not a fact that the percentage of the number of bacterial counts in those analyses was not much less than the percentage of the analyses made by you of the water of the Illinois river at Grafton or at other points?

A. It was.

Q. Could you state approximately the percentage of difference?

A. As near as I can remember the results without immediate access to the figures, there were on an average from seven to ten times as many per cubic centimeter in the water taken from the station at Averyville and also from the mouth of the Illinois river at Grafton as were found in Lake Michigan.

Q. And with reference to the colon bacilli, what do the percentages show?

A. This organism was found much more frequently as a common thing, in the water at Averyville and at Grafton, than in the water of Lake Michigan as examined.

Q. Is it not a fact that it was very infrequently found in the waters of the lake?

A. That is my remembrance. Let me say I have those figures in my satchel if you wish them.

Q. No, I don't care for them at all. I think you are right about it. Was there anything in those determinations made by you of the waters of Lake Michigan, that led you to be-
9362 lieve that the water was infected?

A. I don't think we could call it bacteriologically pure water.

Q. Could you bacteriologically call it water suitable for domestic and drinking purposes in the condition in which you found it at the time the analysis was made?

A. I should not consider it to be very desirable; at least as it exists according to these tests in many instances, it should be a good deal better.

Q. I will ask you professor, if the variations of bacterial count and the variations in the determination of the presence of coli are not very much greater in the waters of the Illinois river than in the waters of Lake Michigan as shown by your analyses of the two waters?

A. I think that is the case.

Q. Profesor, referring to your table of bacterial analyses of the waters of the Illinois river at Averyville for the year 1901, I wish you would explain the significance of the colon bacilli, not having ben found in a sample collected on the 9th day of December, which contained 102,200 bacteria per cubic centimeter, while in the sample collected on the 23rd of September and examined on the 23rd, containing 9,500 bacteria per cubic centimeter, the colon was found, and what particular

significance do you place upon the fact that it is often
9363 not found in samples containing large numbers of bacteria while from the same waters it is often found to be present in samples of water containing small numbers of bacteria per cubic centimeter?

A. I will say that a comparison of the tables will generally show that a large number of colonies of bacteria is accompanied by positive determination of the Bacillus coli-communis, but there are frequent variations from this, and the particular circumstances cited by you as shown by the tests of the Illinois river at Averyville, seem to belong to this unexplainable variation in the results. I should have anticipated, after finding 102,000 bacteria from the water taken on December 9th, that there would be a positive determination of Bacillus coli-communis. Our results based upon the particular samples examined, seemed to show that in these samples it was not present. I should by no means take this to mean that it was absolutely absent in the water from that point at that time commonly. I am not at all surprised to find it present on December 23rd, when the number of colonies as made out was 5,900. The greater variation from the ordinary results is in the first instance. But during the fermentive processes continued for some time there is among the organisms present a survival of the fittest and the special water bacteria are likely to be these which ultimately prevail, while Bacillus coli-communis dies out. This may be one of these instances.

I may say if I may speak generally of this series of investigations at Averyville, for the time from October to De-
9364 cember, 1901, that the number of negative results in the tests for Bacillus coli-communis, is upon the whole, to me quite surprising, taken into account with the total number of colonies that were found at that time.

Q. Now professor, I will ask you to state approximately what relationship the variations of total bacterial count per cubic centimeter in the water of the Illinois river at Averyville for 1901, as shown by your analyses, bear to the bacterial counts of the water drawn from Lake Michigan and analyzed by you in any period?

A. The numbers at Averyville are very considerably greater than those found in the waters of Lake Michigan.

Q. Now as to their variation, professor?

A. And the variation is greater.

Q. Now I will ask you if it is not a fact that where large bacterial counts are obtained, the colon may be present, and yet be masked or overgrown by the other bacteria so that it cannot be detected?

A. Not to any very considerable extent. Bacillus coli-communis by the methods in use has so even and distinct characteristics that it can be pretty certainly found, no matter what else is present.

Q. Professor, you examined bacterially the water of the
9365 Mississippi river at Jefferson Barracks, did you not?

A. Yes sir.

Q. I will ask you to state generally how those results in counts compare with the counts which you obtained from your analyses of the water of the Mississipi river taken at the chain of rocks, Jefferson Barracks being at a point below the city of St. Louis and at a point where the Mississippi river had already taken on the sewage of the City of St. Louis?

A. The number found at Jefferson Barracks is very considerably more than the number at the chain of rocks, as reported in tables 69 to 72 inclusive, for the chain of rocks, and tables 74 to 78 inclusive, for the Jefferson Barracks. I have not figured out these averages, but as I now glance at the tables, the number is from ten to twenty times the number in the latter instance, that is the number for Jefferson Barracks.

Q. Professor, what was the extent of the dilution used by you in making your colony tests?

A. From our experience we diluted the original water to such an extent as should give us from 50 to 100 colonies per plate. Sometimes diluted only 1 to 10; sometimes 1 to 100; sometimes 1 to 1000, according as our previous experience assured us we must do in order to get in the neighborhood of from
9366 50 to 100 colonies to a plate.

Q. Then you would dilute it with pure distilled water, so as to limit the number of colonies developed on the plate to about how many?

A. To from about 50 to 100 was our endeavor.

Q. So that the amount of dilution used in the analyses depended upon the presence of large or small numbers of the bacterial counts contained in the water?

A. The dilution depended upon the supposed number of bacterial counts as indicated by former tests; but of course it is not to be understood that we always did dilute to such an extent that the number was actually limited to 100 or less, but that was our aim.

Q. In making the ordinary gas test it would not be necessary to dilute it in order to detect the presence, would it?

A. It would not.

Q. Do your tables show the per cent of the cubic centimeter of water examined for the purpose of determining the presence or non-presence of this Bacillus coli-communis?

A. These tables do not.

9367 Q. Could you state briefly the quantity used at the various places where the water was obtained that you analyzed?

A. As nearly as I remember, as a general thing, the waters taken from the stations near the head waters were diluted from 1,000 to 10,000 times. Doubtless for some of these it was more than that. At Averyville and Grafton about ten times, and at intermediate points, at varying proportions between these. We did not plate any of this water direct.

Q. Then the tables are not comparative in so far as the same amount of water was used in making the particular examination?

A. If the quantity of water actually examined made any difference, then the tables are not comparative. I take it however, that the method used in the dilution was such that the liability of error in this respect is very small.

Q. How long did you say this Bacillus prodigiosus lived under your experiments?

A. At a maximum of five days, under the conditions of these tests as reported.

Q. Are there different species of the prodigosus?

A. There are different varieties to some extent, but one species.

Q. In other words, the prodigiosus is a species of bacteria?

A. Yes.

9368 Q. And of that species there are different varieties?

A. Yes.

Q. Do you know whether or not those different varieties are different in longevity?

A. I don't think the Bacillus prodigosus is subject to very great variation.

Q. You say you don't think?

A. I don't say. Not nearly so much so as some well known organisms, mention of which has been frequently made.

Q. Do you know whether other bacteriologists have been able to keep it alive longer than five days?

A. I think that has been frequently reported, and I have no doubt but that it is true under other conditions.

Q. It depends then on the conditions in the laboratory to some extent?

A. Considerable. I don't think this is notably an inhabitant of the water at all.

Q. Professor, is there any other source of the colon bacilli other than from the intestinal canal of men and animals so far as you know?

A. It has been reported. It has been found where it did not seem to have orginated in the intestinal canal of men and animals. I have never found it where it did not have
9369 abundant chance to be so derived.

Q. Professor, if it should appear from the analyses of the waters of the Illinois river made at Grafton in the years 1899 and 1900, that there was a larger per cent of the colon bacilli passing down the river at that point in 1900 than there was in 1899, and if it should appear that the colon from the tests and the analyses, showed less frequent the appearances in the waters of the tributaries of the Illinois river for 1900 than in 1899, to what would you attribute the increase in the colon passing down the Illinois river at Grafton during the year 1900 over that of 1899?

A. In such a hypothetical case, as I understand this to be—

Q. Yes, altogether?

A. I should seek for the increased pollution of the main stream somewhere in its course, and if I were to begin this search, I would begin at Grafton and follow the stream upward until such extra pollution could be found.

Q. There would be no possible opportunity for its coming from any other source than from men or animals, would there?

A. Oh yes sir. We know that this organism multiplies in water when the conditions favor, outside of the body. If the question means that it does not come from any other
9370 source ultimately, I don't know that I could assign such
place of its origin, but if the immediate place of origin is to be considered, I should not go beyond the first cultivated field that had been some time previously subject to the contents of the intestinal canal of animals, and where the water had been sufficient for the further multiplication of the organism in the soil.

Q. The conditions for the multiplication in the soil as a general proposition, run about the same, one as with another, do they not?

A. Subject to great variations.

Q. At what temperature does the colon multiply?

A. It multiplies from 20 to 40 degrees centigrade, and somewhat considerably even below the first named degree, that is on the Fahrenheit scale from about 68 if I translate the figures, to 104.

Q. You are not a physician are you professor?

A. I am not.

Q. You never examined the sanitary condition of water other than as here stated by you in your examination of the waters of the Illinois river, Lake Michigan, and the canal and the instances referred to with reference to the various state institutions?

A. Yes, I have made from time to time quite a good
9371 number of examinations of various waters of the state
besides those included in these records.

Q. A long series of examinations?

A. No sir.

Q. Just examined a few samples from each particular place?

A. Since the conclusion of the work in October, 1900, I have, as opportunity permitted, examined a good many samples from various points on the Illinois river, but not for the purpose of any comparison of the number of organisms or for finding Bacillus coli-communis, as to these waters.

Q. Now then, professor, as a bacteriologist, what is the best practical test as shown by the analyses alone, of the presence of typhoid and other water-borne diseases which affect mankind?

A. So far as typhoid fever is concerned, I have been led to the belief and understanding that the detection of Bacillus coli-communis was the best practical test that we had of the possible presence of the organism causing this disease of typhoid fever. Of course there are other organisms sometimes carried in the water which can be readily identified by proper examination, and when they can be identified, that is the best evidence as to whether this water is proper for potable purposes in respect to those particular diseases.

9372 Q. And these results of the analyses and tests showing the presence of the organisms known as the colon bacillus, together with the knowledge of the extent and the source of the pollution above the point examined, or from which the water is taken and analyzed, are the basis or premise of an opinion as to the sanitary condition of that water?

A. Yes sir, that has been my practice, and that of many others, though certain bacteriologists include in their inspection as a regular thing, other particular species.

T. J. BURRILL.

ADJOURNED until 10:00 A. M. following day, Saturday, November 28th, 1903.

10:00 A. M., Saturday, November 28th, 1903.

9373 Continuation pursuant to adjournment.

Present, the Commissioner and same counsel representing the respective parties.

Whereupon, an adjournment was taken until 10:00 A. M. Monday, November 30th, 1903.

10:00 A. M., Monday, November 30 1903.

9374 Continuation pursuant to adjournment.

Present, the Commissioner and same counsel representing the respective parties.

FREDERICK WILLIAM SCHULE,

called as a witness in behalf of the defendants, being first duly sworn by the Commissioner, was examined in chief by Mr. Todd and testified as follows:

Q. What is your name?

A. Frederick William Schule.

Q. What is your business?

A. Student at present.

Q. Where?

A. Ann Arbor,—University of Michigan.

Q. Were you connected with the Chicago University at any time?

A. I was connected with it in the way that I got my position through the Chicago University. I had entered the University of Chicago as a student, and immediately afterwards I obtained the position at Peoria.

9375 Q. Did you ever do any work at Peoria under the direction or supervision of Professor E. O. Jordan of the Chicago University?

A. Yes sir.

Q. And at what time was this work done?

A. It was in the fall of 1901, in the months of October, November and December.

Q. Was that the period wherein the State of Missouri and the State of Illinois and the Sanitary District of Chicago were taking samples by agreement at the same places?

A. Yes sir.

Q. You had charge of the laboratory at Peoria?

A. Yes sir.

Q. Under the direction of Professor Jordan?

A. Yes sir.

Q. This work was bacterial entirely, was it not?

A. Yes sir.

Q. Did you do that work under the direction of Profesor Jordan?

A. Yes sir.

Q. And reported all conclusions from the work to him?

A. Yes.

Q. Analytical data and tables?

A. Yes.

9376 Q. At what points were the samples taken from at Peoria?

A. Two samples were brought each morning, one from above Peoria at the small village of Averyville, and one below at the town of Pekin, Illinois.

Q. Now who were the water takers that brought these samples to the laboratory?

A. The one that brought it from Averyville was a man in connection with the water works there; his name was Martin. He had charge of that.

Q. And who was the man that brought it from Averyville?

A. The man that brought it from Averyville, his name was Lautz; he was in connection with the Pekin waterworks.

Q. From Averyville?

A. No sir, from Pekin.

Q. Who was the fellow from Pekin?

A. Lautz.

Q. And what about the man that brought it from Averyville?

A. His name was Martin.

Q. And these samples were delivered in the laboratory in the Y. M. C. A. building at Peoria?

A. Yes sir.

Q. To you?

A. Yes sir.

9377 Q. And received by you for analysis?

A. Yes sir.

Q. And you received certain instructions from Professor Jordan?

A. Yes sir.

Q. And you followed those instructions?

A. Yes sir.

Q. In the work, did you, that you did?

A. Yes sir.

CROSS-EXAMINATION,

By Mr. Jeffries.

Q. How long had you been studying bacteriology up to that time?

A. Well, practically—fully two years; that was the major subject at Wisconsin.

Q. What was the character of the analyses that you made; what were you looking for?

A. I was taking quantitative analyses and at the same time was taking qualitative analyses, and sending these in to the University of Chicgo; that is, sending samples of the bacteria found, or the cultures.

Q. You were taking both qualitative and quantitative 9378 were you?

A. Yes, I did work in both lines. I determined quantitative cultures at Peoria, and the main work in the qualitative line was done in the University of Chicago, so I understood.

Q. You didn't do any of that then, did you?

A. No sir, very little if any.

Q. I understand you to say then that you made no determinations with reference to the qualitative?

A. Well, I did in so far that I took off the colonies from the plates and shipped them to Chicago for further inspection.

Q. Did you take off the colonies—did you take all the colonies off?

A. All which were different. I tried to take the different colonies off, so as to get a knowledge of the different kinds of bacteria which were found in the waters above and below Peoria.

Q. The different kinds that appeared in the one colony, or different from any that appeared in any of the samples?

A. In any of the samples.

Q. So that if one species or kind appeared in one sample, you would not take that off of the next determination?

A. No sir, about two or three times a week I picked off 9379 samples from the water which was gotten for that day, 9490 Q. State what is shown by table 127 and what is its sanitary significance?

A. Table 127 contains the analyses of samples of water taken from the Illinois river at Morris between January 5th and June 26th, 1900. During the month of January the conditions were not dissimilar to those prevailing during 1899, but the analyses for subsequent days show in several ways the effect of the dilution of the Chicago sewage in the Chicago drainage canal.

The smaller amount of chlorine particularly is evidence of this increased dilution and on several occasions notably in the month of May, the number of bacteria in the Illinois river at this point was lower to a striking degree, than at any time in the preceding period.

Q. How is the great number of bacteria in the month of January and the small number of bacteria in comparison in the months of April, May and June, explained in this table 127?

A. The difference may be in part at least explained by the fact that during the early part of January, 1900, the water from the drainage canal was not flowing into the Desplaines river, but the water from the Illinois and Michigan canal was entering the Desplaines river during that period.

Q. Will you produce table 128 and read it in evidence?

A. Yes sir, table 128 is as follows:

TABLE 128.

9492 Q. State what table 128 shows and its sanitary significance?

A. Table 128 contains the analyses of samples of water from the Fox river at Ottawa between January 4th, and June 25th, 1900.

During the early part of this period the number of bacteria was much higher than in the period of 1899 and much higher than for the latter part of April and for May and June, 1900. This is a phenomenon of common occurrence in river waters and so far as I am aware no adequate explanation for this occurrence has been adduced.

Q. Will you produce and read in evidence table 129?

A. Yes sir, table 129 is as follows:

TABLE 129.

9494 Q. State what table 129 shows and what is its sanitary significance?

A. Table 129 contains analyses of samples of water from the Illinois river at Ottawa between January 4th, and June 25th, 1900. The various determinations chemical and bacterial, especially those showing the amount of albuminoid ammonia, free ammonia and nitrates and the number of bacteria per cubic centimeter, indicate that a considerable change in the direction of purification has taken place between Morris and Ottawa as in 1899.

Q. Will you produce and read in evidence table 130?

A. Yes sir, table 130 is as follows:

TABLE 130.

9496 Q. Will you please explain what table 130 shows and its sanitary significance?

A. Table 130 contains analyses of samples of water from the Big Vermillion at LaSalle, the samples being taken between January 2nd, and June 26th, 1900. The number of bacteria during this period is on the whole higher than in the period for 1899. The amount of free ammonia during the first part of this period is much higher than in the latter part of the period.

Q. Will you produce and read in evidence table 131?

A. Yes sir, table 131 is as follows:

TABLE 131.

STREAMS EXAMINATION—CHICAGO SANITARY DISTRICT.

9498 Q. What does table 131 show and what is its sanitary significance?

A. Table 131 contains analyses of samples of water from the Illinois river at LaSalle between January 2nd, and June 26th, 1900. During the months of January, February and March, the number of bacteria in the rivers is, as in the other river waters that have been considered, much higher than during 1899. The amount of free ammonia is likewise much higher during the first part of this period than during the latter portion.

Q. Will you produce and read in evidence table 132?

A. Yes sir, table 132 is as follows:

Table 132.

9500 Q. State what table 132 shows and its sanitary significance?

A. Table 132 contains analyses of samples of water from the Illinois and Michigan canal at LaSalle from January 2nd to June 26th, 1900. I should like to strike out in table 131 the height of water in the Illinois river at LaSalle for February 6th, as being obviously a clerical error.

Q. Will you produce and read in evidence table 133?

A. Yes, sir, table 133 is as follows:

TABLE 133.

STREAMS EXAMINATION—CHICAGO SANITARY DISTRICT.

SANITARY WATER ANALYSIS—PARTS PER MILLION.

SOURCE OF WATER—ILLINOIS RIVER, HENRY.

9502 Q. State what table 133 shows and its sanitary significance?

A. Table 133 contains analyses of samples of water from the Illinois river at Henry between January 3rd and June 25th, 1900. Here again is shown the increase in the number of bacteria in the river water during the late winter and early spring. This has already been shown to be a common phenomenon in river water and occurs in the tributaries of the Illinois as well as in the Illinois itself. The diminished chlorine in the latter part of this period shows the effect of the dilution due to the opening of the Chicago drainage canal.

Q. Will you produce table 134 and read it in evidence?

A. Yes sir, table 134 is as follows:

TABLE 134.

9504 State what table 134 shows and its sanitary significance?

A. Table 134 contains analyses of samples of water in the Illinois river at Averyville from January 2nd to June 26th, 1900. Both the effects of purification and dilution are shown in this table, especially during the latter part of the period when the effect of the condition of early spring had disappeared.

Q. Will you produce and read in evidence table 135?

A. Yes sir, table 135 is as follows:

TABLE 135.

9506 Q. State what table 135 shows and its sanitary significance?

A. This table contains analyses of samples of water in the Illinois river at Wesley City. The smaller number of bacteria during this period as compared with the 1899 period shows that the pollution entering the Illinois river at Peoria, has been crowded in part towards the western bank and does not make its presence so evident in mid-stream as was the case during 1899.

Q. Will you produce and read in evidence table 136?

A. Yes sir, table 136 is as follows:

TABLE 136.

STREAMS EXAMINATION—CHICAGO SANITARY DISTRICT.

9508 Q. State what table 136 shows and its sanitary significance?

A. This table contains the analyses of samples of water taken from the Illinois river at Pekin from January 11th, 1900 to June 27th, 1900.

The effect of pollution here in the mid-stream sample is more manifest than in the samples from Wesley City owing possibly to a more thorough mixing at this point.

Q. Will you produce and read in evidence table 137?

A. Yes sir, table 137 is as follows:

TABLE 137.

9510 Q. State what table 137 shows and what its sanitary significance is?

A. This table contains analyses of samples of water taken from the Illinois river at Havana, between January 11th and June 27th, 1900. The purification in the river as shown by the amount of nitrates and the number of bacteria is manifest here as well as in the 1899 period.

Q. Will you produce table 138 and read it in evidence?

A. Yes sir, table 138 is as follows:

TABLE 138.

9512 Q. What does table 138 show and what is its sanitary significance?

A. Table 138 contains the analyses of samples of water from the Sangamon river at Chandlerville, from January 3rd, and June 27, 1900. The usual spring increase in the number of bacteria is manifest at this point as in the other tributaries of the Illinois and in the Illinois river itself.

Q. Will you produce and read in evidence table 139?

A. Yes sir, table 139 is as follows:

TABLE 139.

9514 Q. State what table 139 shows and what is its sanitary significance?

A. Table 139 contains analyses of samples of water from the Illinois river at Beardstown from January 4th to June 28th, 1900. Taking into consideration the greater dilution of the water at this point, the analytical data are not materially different from those covering the 1899 period.

Q. Will you produce and read in evidence table 140?

A. Yes sir, table 140 is as follows:

TABLE 140.

9516 Q. State what table 140 shows and its sanitary significance?

A. Table 140 contains analyses of samples of water taken from the Illinois river at Kampsville from January 3rd to June 27th, 1900. The usual spring rise in the number of bacteria, the amount of free ammonia and albuminoid ammonia and so on, is manifest here as elsewhere, but during the latter part of the period the condition of the water both chemically and bacterially compares very favorably with that in the 1899 period.

Q. How do the chemical and bacterial constituents of the water at Kampsville, as manifest by this table compare with the conditions for this period at Averyville?

A. The number of bacteria averages less at Kampsville than at Averyville. The amount of free ammonia is on the whole lower. The albuminoid ammonia is very similar; thus, on June 19th at Averyville, the albuminoid ammonia was .264.

And on June 22nd, at Kampsville, the albuminoid ammonia was .264.

And on June 26th at Averyville the albuminoid ammonia was .264.

And on June 27th at Kampsville, the albuminoid ammonia was .264.

The nitrates are on the whole lower at Kampsville than at Averyville during this period.

The nitrites are also lower, and the oxygen consumed
9517 on the whole does not differ materially.

ADJOURNED until 10:00 A. M. following day, Tuesday, December, 1st, 1903.

9518 10:00 a. m., Tuesday, December 1st, 1903. Continuation pursuant to adjournment.

Present, the Commissioner and same counsel representing the respective parties.

PROF. EDWIN O. JORDAN,

resumed the stand for further direct-examination, by Mr. Todd, and testified as follows:

Q. Professor, will you produce and read table 141 in evidence?

A. Yes, it is as follows:

TABLE 141.

STREAMS EXAMINATION—CHICAGO SANITARY DISTRICT.

SANITARY WATER ANALYSIS—PARTS PER MILLION.

SOURCE OF WATER—ILLINOIS RIVER, GRAFTON.

Report of EDWIN O. JORDAN, University of Chicago.

9520 Q. State what table 141 shows and its sanitary significance?

A. Table 141 contains analyses of samples of water from the Illinois river at Grafton, taken between January 4th, and June 29th, 1900.

A very considerable degree of purification is shown chemically, and in the latter part of the period bacterially also, as compared with the collecting stations in the upper stretches of the river. The increased volume of water in the Illinois river, especially in the months of March and April, is reflected in the lower chlorine content during this period.

Q. Will you produce and read in evidence table 142?

A. Yes, it is as follows:

TABLE 142.

9522 Q. State what table 142 shows and its sanitary significance?

A. Table 142 contains analyses of samples of water taken from the Mississippi river at Grafton, Illinois, the samples being collected between January 4th and June 29th, 1900.

The amount of albuminoid ammonia in the water of the Mississippi during this period is on the whole somewhat higher than the amount in the Illinois river in samples taken on similar dates.

Q. Will you produce and read in evidence tables 143, 144, 145, 146 and 147, showing the cross-section of the Mississippi river at Alton?

A. Yes, they are as follows:

TABLE 143.

9528 Q. State what these tables show and their sanitary significance?

A. Tables 143 to 147, inclusive, show the analyses of a series of five samples taken at approximately equi-distant points, across the Mississippi above Alton, Illinois.

The points of collection were the same as during the 1899 period.

The analyses show that as in the 1899 period, there is a lack of complete commingling of the waters of the Illinois and Mississippi rivers at this point, the water derived from the Illinois river clinging as before, to the left bank of the Illinois shore, as is shown particularly by the chlorine and nitrate determinations.

Q. Will you produce and read table 152?

A. Yes, it is as follows:

TABLE 148.

STREAMS EXAMINATION—CHICAGO SANITARY DISTRICT.

9528 Q. State what these tables show and their sanitary significance?

A. Tables 143 to 147, inclusive, show the analyses of a series of five samples taken at approximately equi-distant points, across the Mississippi above Alton, Illinois.

The points of collection were the same as during the 1899 period.

The analyses show that as in the 1899 period, there is a lack of complete commingling of the waters of the Illinois and Mississippi rivers at this point, the water derived from the Illinois river clinging as before, to the left bank of the Illinois shore, as is shown particularly by the chlorine and nitrate determinations.

Q. Will you produce and read table 152?

A. Yes, it is as follows:

TABLE 152.

STREAMS EXAMINATION—CHICAGO SANITARY DISTRICT.

SANITARY WATER ANALYSIS—PARTS PER MILLION.

SOURCE OF WATER—MISSOURI RIVER, FORT BELLEFONTAINE, WEST ALTON, MO.

9530 Q. State what table 152 shows, and its sanitary significance?

A. Table 152 contains the analyses of samples of water taken from the Missouri river at Fort Bellefontaine, West Alton, Missouri, between January 4th and June 27th, 1900.

The large amount of suspended matter carried by the Missouri river in high water periods is shown by these determinations, especially by the suspended residue on evaporation, by the amount of oxygen consumed by suspended matter, and by the amount of nitrogen present in the form of albuminoid ammonia in suspended matter. Throughout the greater part of this period also the number of bacteria in the Missouri river water was high.

Q. Will you produce and read in evidence tables 148, 149, 150 and 151?

A. Yes; they are as follows:

TABLE 148.

STREAMS EXAMINATION—CHICAGO SANITARY DISTRICT.

9535 Q. State what these tables show and their sanitary significance?

A. Tables 148, 149, 150, and 151 contain analyses of samples of water taken from the Mississippi river opposite the pumping station of the St. Louis waterworks at the chain of rocks between January 5th and, June 28th, 1900, the samples being collected from the same points as were specifically designated for the 1899 period.

The considerable amount of suspended matter, as is shown by the residue on evaporation, which was present in the water of the Mississippi river at the inlet tower and in midstream at this point, when compared with the smaller amount of suspended matter in the Mississippi river above the entrance of the Missouri, indicates that the major part of the water entering the St. Louis water intake during the period covered by these analyses was derived from the Missouri river rather than from the Illinois.

Q. Will you produce and read in evidence tables 153, 154, 155, 156 and 157?

A. Yes, they are as follows:

TABLE 153.

9541 Q. State what these tables show and what is their sanitary significance?

A. Tables 153, 154, 155, 156 and 157 include analyses of samples of water taken from the Mississippi river at Jefferson Barracks, Missouri, below the City of St. Louis, between January 4th and April 26th, 1900, the points at which the samples were collected being the same as those specified more particularly for the 1899 period. Aside from the changes attributable to the differences already noted in the composition of the Illinois, Mississippi and Missouri river waters, the analyses at this point contained nothing of special significance?

Q. Will you produce and read in evidence table 158?

A. Yes, it is as follows:

TABLE 158.

9543 Q. State what table 158 shows, and its sanitary significance?

A. Table 158 contains analyses of samples of water drawn from the tap at St. Louis, Missouri, the samples being collected between January 4th, and June 28th, 1900.

The large amount of suspended matter in the water of the Missouri river during the latter part of this period is reflected in the increased residue on evaporation in suspended matter in the tap water, although the reduction in passage through settling basins is very great.

Q. Professor, you have now read in evidence all the tables containing the analytical results for the two periods, 1899 and 1900, that you made for the determination of such as you have heretofore stated, have you not?

A. I have.

MR. JEFFRIES: I move to strike out tables 81 to 158, inclusive, read into the evidence by Professor Jordan, for the same reasons stated in my motion to strike out the tables introduced and read into evidence by Professors Long and Zeit, my understanding being that these tables cover the same period and the same character of analyses.

I move to strike out all the tables and all conclusions and inferences drawn from the tables which have reference to the chemical and bacterial analyses of the waters of the tributaries of the Illinois river, for the same reasons stated in previous objections to the introduction of testimony with reference to
9544 the sanitary condition of the waters of the tributaries of the Illinois river.

Q. MR. TODD: Professor, will you explain what the different chemical constituents as disclosed by the tables just introduced mean, and their sanitary significance, as well as the physical and bacterial determinations and their sanitary significance, as applied to the streams under investigation?

A. The physical characters of the water have been roughly determined with reference to the amount of turbidity, amount of sediment, the color and odor.

Little or no sanitary importance can be attached to the turbidity, sediment and color in the cases under consideration.

As regards the odor of the water, it is found that, in general, waters containing a large amount of organic matter in the early

stages of decomposition, possess an offensive odor readily perceived by the senses, while less impure waters or waters further advanced in the processes of oxidation possess little odor, or, it may be, none at all. It sometimes happens, however, that waters containing a large number of microscopic forms of life, chiefly algae and infusoria, yield odors that are more or less offensive, and that simulate the odors of decomposition. The death and disintegration of these microscopic forms may likewise be the cause of disagreeable smells. Offensive odors, then, may
9545 or may not be accompanied by dangerous sanitary qualities.

Turning next to the various chemical determinations, we may first consider the residue on evaporation. This determination gives information as to the amount of solid substance remaining after the water in which it was dissolved or suspended has been completely evaporated. During the process of thorough drying, certain substances, organic and mineral, are decomposed and driven off.

In general polluted waters contain a rather high residue on evaporation, but in certain cases the residue on evaporation may have reference simply to harmless mineral matters in suspension. In all cases a distinction was made between the dissolved residue on evaporation and the suspended residue on evaporation, the determinations being made both upon filtered and unfiltered samples, the difference between the two being taken as the weight of the residue in suspension.

The determinations of chlorine may next be considered. Chlorine is present in practically all natural waters in combination with sodium in the form of sodium chloride or common salt. Owing to the large amount of salt in urine and in various forms of household waste, it has been found that sewage contains an amount of chlorine in marked excess of that present in most natural and unpolluted ground and surface waters.

9546 When the amount of chlorine normally present in the unpolluted wells and springs of a given district is accurately known, it becomes possible to determine with a considerable degree of precision the amount of pollution existing in the various ground and surface waters of that region which have received a larger or smaller amount of drainage.

The content of a water in sodium chloride is therefore under some conditions a fairly satisfactory gauge of the sanitary condition of that water. Owing to the permanence of the salt, however, the amount of chlorine in a polluted water does not afford conclusive indications as to whether the pollution is recent or remote. In following the passage of salt down stream in a polluted river, the permanency of this substance renders it a valuable indication of the degree of dilution and mixing, but on the other hand, does not afford a clue to the rapidity and extent with which processes of oxidation and bacterial purification are taking place.

The determinations known as oxygen consumed concerns especially the carbonaceous matter in the water.

The significance of this determination lies in its comparative rather than its absolute value, since the amount of oxygen consumed as determined by the quantity of permanganate solution consumed during heating, is affected materially by the period of heating, and by other factors. Exact uniformity of the analytical processes involved is therefore of great import-
9547 ance, and in order that the results in one and the same
laboratory shall be strictly comparable throughout it is necessary to maintain perfect uniformity of procedure. The changes taking place in carbonaceous matter in a water cannot be followed step by step as is the case with the nitrogenous compounds, since the carbon di-oxide formed in decomposition processes either goes off, or enters into combination with mineral elements.

The most significant organic compounds in a polluted water are those of nitrogenous character. These nitrogenous compounds are usually determined in four different states, as albuminoid ammonia or organic nitrogen, as free ammonia, as nitrites and as nitrates.

If we follow the history briefly of the waste nitrogenous compounds discharged from the animal body it is as follows:

These compounds are at first relatively complex and are chemically highly organized bodies. When subjected to bacterial action free ammonia is liberated from these substances, and enters into loose combination with certain of the elements present in the water or sewage. When a water into which such matters have been received a short time before is heated, the ammonia is driven off in the steam and can be collected and measured with a considerable degree of accuracy.

This is the so-called free ammonia in the analytical tables.

9548 The nitrogen in the more chemically complex substances on the other hand, is for the most part not driven off by this process. This is the so-called albuminoid ammonia, the amount of which, however, can be determined by heating in an alkaline solution in the presence of permanganate, destruction of the albumin or nitrogenous molecule taking place under these conditions. This process results in the liberation of ammoniacal compounds which can then be distilled over, collected and measured by the same method as used for the determination of the free ammonia.

In general it may be said that a fresh sewage contains a relatively large proportion of nitrogen in the form of albuminoid ammonia, while a stale sewage contains a smaller proportion of nitrogen in the form of albuminoid ammonia, bacterial activity having converted the albuminoid ammonia into free ammonia.

These early stages in the decomposition of organic matter are followed by oxidation processes which result in the conversion of the free ammonia of the water into nitrites, nitrites being less highly energized compounds than the ammoniacal compounds from which they have been derived. The reason for this oxidation process resides in the need of bacteria for food. Food being matter containing available potential energy, many kinds of bacteria are able to obtain this energy from the ammonium compounds.

9549 Under favorable conditions the process of oxidation does not stop here, as certain bacteria are able to obtain the energy necessary for their development even from compounds containing so little available potential energy as nitrites, and are able to carry on their vital processes with the aid of the energy derived from the oxidation of the nitrites, which by virtue of this bacterial activity are converted into mineral nitrates, the nitrogen then passing successively through the various stages of albuminoid ammonia, free ammonia, nitrites and nitrates. The oxidation of the free ammonia into nitrites and of the nitrites into nitrates is what is termed the process of nitrification. The importance of these facts from the sanitary side is due to the connection of these oxidation processes with processes of purification.

In general, large amounts of albuminoid and free ammonia, indicate the existence of products of decomposition, while the presence of a large amount of nitrate, together with little free and albuminoid ammonia and little nitrite, characterizes a water which may perhaps in the past have received a considerable quantity of polluting matter, but which after the lapse of time, and through bacterial activity has become relatively stable. It has been found empirically that waters in which these oxidation processes have taken place, less commonly give rise to disease, or are a source of danger, than waters that have received
9550 recent pollution, as indicated by the relatively high amounts of free and albuminoid ammonia.

The number of bacteria in a water is usually determined by mixing an accurately measured quantity of the water with nutrient beef jelly and then pouring the mixture out into a sterilized glass dish. The theory underlying this procedure is that each germ originally present in the water, finding itself in a favorable nutrient medium, grows, multiplies and in a few hours or days has formed about itself a growth or colony large enough to be plainly visible to the naked eye.

Different kinds of bacteria form colonies that can be distinguished, one from another, by various physical characters. The kinds of bacteria in a water vary greatly in their sanitary significance, most being perfectly harmless saprophytic forms, which do not so far as is known, have any injurious effect upon the human system, even when taken into the alimentary tract in large quantities. Others, the poisonous or so-called pathogenic germs, are able when taken into the animal body, under suitable conditions, to produce poisonous substances which damage the organism.

The number of bacteria per cubic centimeter as enumerated in the analytical tables 81 to 158 includes the colonies of
9551 all kinds developing upon the bacterial plates, no distinction being made between the harmless and injurious kinds.

By enumerating the number of colonies occurring on one of these plates of beef jelly or nutrient gelatin, some approximation can be arrived at regarding the number of germs originally present in the water, although the absolute number of bacteria

in a water is not always convincing evidence of the sanitary quality of water, since under certain laboratory conditions, bacteria may be made to multiply in a pure water. At the same time experience has shown that in waters collected under natural conditions from springs, rivers, lakes and reservoirs, the purer waters contain fewer bacteria, while those waters that are polluted with sewage or large quantities of organic matter, contain numbers of bacteria much in excess of those found in purer waters. Under natural conditions, it is in general true, that as the food supply of bacteria diminishes, the number of germs becomes fewer, while an influx of food material favors the longevity of certain bacteria and their further multiplication. Surface waters contain as a rule, larger numbers of bacteria than ground waters, which have been freed of a portion of their bacterial content by filtration through layers of sand or soil. It has been observed that the water of a sewage polluted river may contain large numbers of bacteria just below the source of the pollution, but that these numbers diminish with the pass-
9552 age of the water down stream.

Q. Have you made a table of comparative averages of the different chemical and bacterial analyses from the tables 81 to 158, both inclusive, for the years 1899 and 1900?

A. I have.

Q. Will you produce and read in evidence such table?

MR. JEFFRIES: Now, I object to the production and reading into the evidence by this witness of the table referred to by him and known as table E, which is a table of comparative averages of the chemical and bacterial analyses of the water in question for a part of the year 1899, and part of the year 1900, for the reason that such table of averages is not competent evidence in this case, the averages for the two years not being comparable with each other on account of there being nine months covered for the year 1899, to-wit, April to December, inclusive, and only three months for the year 1900, to-wit, January until March, inclusive, and I object to the table being read into evidence for the further reason that a table of averages constitutes no evidence, for the reason that it fails to disclose the bacterial and chemical condition of the water at certain time, which are as important in the determinations of this case as for the determination of the chemical and bacterial condition of the water at any other

time, and the table of comparative averages cannot be relied upon because it conceals and fails to reveal all of the con-
9553 ditions chemically and bacterially of the waters in question at all times during any one year or any one period of time.

In addition to the foregoing objection I will also state that the table of comparative averages above referred to is incompetent for the reason that analyses chemical and bacterial of the waters in question at the various points mentioned in the table, are not comparable with each other because covering different dates and different periods of time, for the two years.

MR. TODD: Will you produce and read such table in evidence?

A. Yes, this table of averages is designated as table E and table E continued, and is contained on two sheets. The table is as follows:

TABLE E.

ERRATA.

Under free ammonia, next to last line, should be .128 instead of 12.83.

Under free ammonia, last line, should be .337 instead of 3.37.

Under albuminoid ammonia, total, third figure from bottom, should be .347 instead of 3.47.

Under albuminoid ammonia, total, second figure from bottom, should be .245 instead of 2.45.

9556 Q. What do the tables and table of averages read into the record by you show, as to the purification of the waters of the Illinois river for the period of 1899, interpreting the sanitary significance of the different chemical and bacterial constituents which you have heretofore explained?

MR. JEFFRIES: I object to the question for the same reasons stated in my objection to the reading of the table into evidence, and I object to the witness drawing any conclusions or inferences from the tables and stating such conclusions and inferences in evidence, and I object to his drawing any conclusions from the tables of averages because such tables conceal and fail to reveal the condition of the water in the Illinois river both chemically and bacterially at all times during the period analyzed or covered by the table of averages, and I object to his drawing any conclusions or inferences from the tables of analyses which have been read into the evidence for the same reasons stated in my objection to the introduction of such table in evidence.

Q. (Question repeated.)

A. From an examination and consideration of the tables of separate analyses and the tables of averages for this period, the period of 1899, it appears that the water in the Illinois and Michigan canal at Bridgeport and at Lockport, as well as
9557 the water of the Desplaines river at Joliet and of the Illinois river at Morris, contained throughout this period a large amount of nitrogenous organic matter in the early stages of decomposition. It appears also from the large amount of chlorine present in these waters that the initial pollution of the Illinois river reached a considerable height during this period. The large number of bacteria present in these waters shows that the substances capable of serving as food for these organisms were present in great abundance.

The tables and averages also show that by the time the Illinois river reaches Ottawa, being somewhat diluted in its course by the purer waters of the Kankakee, mingling with which is incomplete at Morris, a very great change has taken place in the composition of the river water, a change which is manifested especially by the diminution in the amount of albuminoid ammonia by the increase in the amount of nitrites and nitrates, and particularly by an enormous and significant diminution in the bacterial content.

The oxidation of the organic matter continues with the passage of the water down stream and by the time the flow reaches Averyville the amount of free ammonia is greatly diminished
as compared with the amount at Ottawa. The amount of
9558 albuminoid ammonia is diminished. The amount of
nitrites is somewhat lower than it was at Ottawa; the
amount of nitrates has greatly increased, while the bacteria which were present in such enormous numbers in the waters of the upper Illinois have now sunk to a point where they can be compared with the number present in ordinary surface waters in the United States and with the number present in the tributaries of the Ilinois during this period.

Below Averyville the Illinois river receives a large influx of polluting material from Peoria with its stock yards and distilleries, which is evidenced by the increase in some of the significant constituents in the river water, notably in the free ammonia and the albuminoid ammonia and in the number of bacteria.

At Pekin some additional pollution is received and the mingling of the Peoria sewage with the Illinois river water has become more perfect. From Pekin to the mouth of the river, the purification follows a generally progressive course, until by the time the mouth of the river is reached at Grafton, the amount of free and albuminoid ammonia, the oxygen consumed by the carbonaceous matter and the number of bacteria are again low, while the relatively large amount of nitrates bears witness to
the practically complete oxidation of the enormous amount
9559 of organic matter with which the sewage was laden at
Peoria, as well as that with which it originally set forth
at Lockport.

MR. JEFFRIES: Now, I move to strike out the answer of the witness to the last question for the reason that it can have no bearing upon the issues involved in this case, in that the physical condition of the Illinois river has materially changed by the opening of the Chicago drainage canal. All of the evidence of the defendants' witnesses along the Illinois river showed that during the greater part of the year 1899, and for several years prior thereto, the water in that river from Kampsville to Henry Dam was in a state of practical quiescence, thus affording greater opportunities for the disappearance and destruction of pathogenic bacteria than in any period since 1899.

I move to strike out the answer for the further reason that an opinion based upon such conditions as pertained to the river at that time for the purposes of showing the pathogenic bacteria or disease producing organisms did not reach the Mississippi river and the chain of rocks during that period, is no evidence that such disease producing organisms and bacteria are not now and have not since the opening of the Chicago drainage canal, appeared in the waters of the Mississippi river
9560 at the chain of rocks coming from the sewage of Chicago.

Adjourned until 2:00 p. m., same day, Tuesday, December 1st, 1903.

9561 2:00 p. m., Tuesday, December 1st, 1903. Continuation pursuant to adjournment.

Present, the Commissioner and same counsel representing the respective parties.

PROF. EDWIN O. JORDAN,

resumed the stand for further direct-examination, by Mr. Todd, and testified as follows:

Q. For the period of 1900?

MR. JEFFRIES: I object to the witness drawing any conclusions or inferences and stating such conclusions and inferences in the testimony from the tables of averages for the year 1900, or during the months the water was analyzed for the year 1900, for the reason that such table of averages does not disclose the actual conditions, chemical or bacterial in the waters of the Illinois river at any and all times during that year or during the time the analyses were carried on.

I object for the further reason that such table of averages is not comparable with any condition that may be shown from one analysis, either bacterial or chemical, or any series of analyses for the reason that the witness has not taken into 9562 consideration in making these determinations the various and varying conditions physical and otherwise of the water in the Illinois river, and I object to the witness drawing any conclusions from the tables of analyses referred to in the question and heretofore introduced in evidence for the same reasons stated in my objection to the reading of such tables into the record, together with the reasons suggested by me in my objection to the drawing of inferences and stating of conclusions from the table of averages made up of the tables of analyses so referred to in the question.

Q. (Question repeated.)

A. The conditions in the Illinois river during the larger part of the period covered by these investigations are shown by analyses of samples collected at the same points and under the same conditions as in 1899, the whole series of analyses from May, 1899, to the end of June, 1900, forming one continuous period.

From April to June, 1900, analyses were made of the water from the Chicago drainage canal at Kedzie street and at Lockport. These analyses show that as compared with the condition of the water in the Chicago river considerable dilution has taken place as witnessed particularly by the chlorine determination, as well as by similar changes in the other constituents of the sewage.

9563 A mingling of the waters coming from the Chicago drainage canal at Lockport and from the Illinois and Michigan canal at Lockport, with the waters of the Desplaines river which is subsequently joined by the Kankakee, took place during this period. The first admixture of the waters of the drainage canal took place on the 17th of January, 1900, after the canal had been filled, and the gates finally opened.

Examination of the separate analyses of the samples of water from the Illinois river at Morris and also of the averages of these analyses, shows that the water of the river at this point was charged with organic matter; that it contained a large amount of nitrogen in the form of albuminoid and of free ammonia; that the amount of oxygen consumed was high, and that the number of bacteria was still large.

The samples of water taken from the Illinois river at Ottawa during this same period showed that considerable purification took place between Morris and Ottawa, the amount of free ammonia and of albuminoid ammonia and of oxygen consumed, being diminished, and the number of bacteria being little more than one-fourth the number in the Illinois river at Morris during this same period.

By the time Averyville is reached, the process of purification had proceeded still farther, both free and albumi-
9564 noid ammonia being notably lower than at Ottawa.

At this station also the amount of nitrate was high, showing that considerable nitrification had taken place in the flow from the drainage canal to this point. The number of bacteria was not half as great as in the Illinois river at Ottawa during this same period.

A further addition of polluting water took place at Peoria and Pekin, with the result that in the lower half of the river the process of purification had again to be completed. How complete this purification was may be seen from the determinations at Grafton for this period, the amount of free and albuminoid ammonia in the water and the amount of nitrates indicating that this purification followed a parallel course to the purification in the upper half of the river.

This second period, the conditions in which have been just described, has been arbitrarily separated from the first period, namely, that for the months May to December 1899, but the analyses show plainly that the essential course of events in the water of the Illinois river is the same, whether a period of two months, or five months or fourteen months, be considered.

In all cases the same phenomenon is noticed. The water at the outset, highly charged with putrescible or-
9565 ganic matter and laden with sewage material, regains in the course of about 130 miles flow the condition usually existing in surface waters in this country.

The entrance for a second time into this stream of a large mass of polluting matter, an event that occurs at Peoria and Pekin as heretofore pointed out, is followed by a second successful attempt on the part of the stream to purify itself of this added load.

The self-purification of the Illinois river during the period covered by this analysis extending from May, 1899, to the end of June, 1900, is notable in character and extent both at high water and at low water, both at low temperatures and at high temperatures, and shows convincingly that under the conditions prevailing in the Illinois valley during the period studied, the self-purification of streams is not an interesting biological myth, but an actual and definite occurrence.

Q. Professor, while these tables have been presented as covering two periods of investigation, as a matter of fact the investigation covers one period, does it not?

A. It certainly does. There was practically no break in the analyses, as they were conducted in my laboratory from May, 1899, to the end of June, 1900, weekly analyses being made throughout this period, with but few exceptions.

9566 Q. Are there any two periods during the course of this examination from May, 1899, to June, 1900, that are comparable with each other as to height of water, temperature and similar conditions?

A. Yes, there are.

Q. Will you point out the periods, give the analytical data and make the comparison?

A. In examining the analytical data for Grafton, Illinois, table 101, it appears that the height of water in the Ilionis river at this point was much greater in May and June, 1899, than in July, August, September, October, Noevmber and December, 1899.

Referring next to table 141 containing the analyses of samples from the Illinois river at Grafton for 1900, it appears that the water was very much higher in the months of March and April than in the months of January, February, May and June.

On comparing the temperatures of the water it appears that the temperature was very much higher in June, July, August and September, 1899, and in May and June, 1900, than it was in October, November and December, 1899, and January, February and March, 1900.

9567 Comparing the analytical data it appears that the free ammonia was very high in January, 1900, and in the latter part of November and early part of December, 1899, and that it was relatively low in June and August, 1899, and May and June, 1900.

It appears further that the oxygen consumed was relatively high in May and June, 1899, and in February and March, 1900, and that the nitrates were relatively high in November and December, 1899, and in January, 1900.

It appears further that the number of bacteria per cubic centimeter as determined by the colony count was high in June, 1899, in the latter part of December, 1899, and from about the middle of January to the last of March, 1900, while they were relatively low in August, September, October and November, 1899, and in early January, and in April, May and June, 1900.

From a comparison of the analytical data therefore, at this point, it is evident that the separation of the two periods on the basis of calendar years, is from the point of view of sanitary water analysis, an arbitrary one, and does not bear any definite relation to any meteorological or biological conditions.

Q. How does the chemical and bacterial condition of the
9568 Illinois river at Averyville, Kampsville and Grafton, for the period covered by this survey, compare with that of its tributaries for the same period?

MR. JEFFRIES: I object to the question for the reason that the issue involved in this case is not the determination of the sanitary condition of the waters of the tributaries of the Illinois river, the sanitary condition of the waters of those tributaries being a matter of no importance so far as the issues in this case are concerned, and I object to the question for the further reason that the subject of infection is eliminated therefrom.

Q. (Question repeated.)

A. So far as the chemical and bacterial determinations show, the condition of the Illinois river at Averyville, Kampsville and Grafton, differs in but slight and insignificant particulars from the waters of the tributary streams, thus the amount of albuminoid ammonia in the water of the Kankakee river at Wilmington for June to December, 1899, is .352.

At Averyville for the same period, it is .447

At Grafton for the same period, it is .400

The oxygen consumed in the Fox river at Ottawa for the
period May to December, 1899, was 8.3
9569 In the Illinois river at Averyville, 8.6
in the Illinois river at Grafton, 7.8

The number of bacteria in the Kankakee river at Wilmington
from June to December, 1899, was, 5,000
In the Fox river at Ottawa, 6,500
Big Vermillion river at La Salle, 7,970
Sangamon river at Chandlerville, 5,080
Illinois river at Averyville, 3,670
Illinois river at Kampsville, 4,810
Illinois river at Grafton, 10,210

For the period January to June, 1900, the albuminoid ammonia
in the Kankakee river at Wilmington, was .327
In the Fox river at Ottawa, .42
In the Big Vermillion river at La Salle, .285
In the Sangamon river at Chandlerville, .239

The amount of albuminoid ammonia in the Illinois river at
Averyville for January to June, 1900, was .366
At Kampsville, .445
At Grafton, .423

While the average number of bacteria in the Kankakee river
at Wilmington from January to June, 190, was 16,100
The Fox river at Ottawa, 20,600
Big Vermillion river at La Salle, 19,200
Sangamon river at Chandlerville, 24,200

9570 While the average number of bacteria per cubic centimeter
for January to June, 1900, in the water of the Illinois
river at Averyville was, 51,800
At Kampsville, 33,700
At Grafton, 21,100

The number of bacteria in the Illinois river at Grafton being lower than the number in the Sangamon river at Chandlerville, and almost exactly the same as the number in the Fox river at Ottawa, and the Big Vermillion river at La Salle for this period; so that considered from the point of view of a comparison of the chemical and bacterial analyses the condition of the Illinois river at Averyville, Kampsville and Grafton, compares favorably with the important tributaries of the Illinois.

Q. How does the condition of the Illinois river at Pekin compare with the conditions that obtain at Averyville?

A. Throughout the period covered by this investigation, namely, from May, 1899, to the end of June, 1900, the water of the Illinois river at Pekin was usually in a more highly polluted condition chemically and bacterially, than the water of the Illinois river at Averyville.

Q. What explanation, if any, have you for that condition at Pekin?

9571 A. The large amount of sewage and refuse that enters the Illinois river at Peoria and at Pekin offers a sufficient explanation in my opinion for the increased pollution of the Illinois river at this point as compared with the condition of the river above Peoria, at Averyville, before this pollution enters.

Q. How far down the river from Peoria does the pollution which the Illinois river takes on at Peoria, disappear?

A. That is a somewhat difficult question to answer, because the conditions undoubtedly vary at different times of the year and with different rates of flow. The water of the Illinois river at Havana is on the whole, considered in the light of the chemical and bacterial examinations given in these tables, in a less satisfactory condition than the water of the Illinois river at Averyville.

The same might possibly be said on some occasions, of the water of the Illinois river at Beardstown; at Kampsville and at Grafton. However, the water of the Illinois river at Grafton is usually in a condition very similar to that obtaining at Averyville.

Q. How far from Peoria is Kampsville?

A. About 124 miles.

Q. How far is Averyville from Lockport?

A. About 130 miles.

9572 Q. During this entire period, do your chemical and bacterial examinations disclose the presence at Kampsville of the sewage from Chicago, whether from the Illinois and Michigan canal for the first part of this period, or from the Chicago main drainage canal for the second?

A. They do not so far as the number of bacteria in the water is concerned, nor do they so far as the various chemical determinations of albuminoid ammonia, oxygen consumed, nitrites and nitrates are concerned. The large amount of chlorine that enters the Desplaines river along with the Chicago sewage, is, however, permanent, and not being liable to destruction by various influences, as is the case with the nitrogenous organic matter and the bacteria, that are added in the Chicago sewage, the chlorine manifests itself at Kampsville and Grafton, and even beyond, into the Mississippi river.

MR. JEFFRIES: I move to strike out the last preceding answer for the reason that the witness has not undertaken to differentiate between the bacteria or germ life of a pathogenic character and those of the non-pathogenic character, and particularly in reference to the longevity of both.

9573 MR. TODD: In reply to that objection I will state that before the witness leaves the stand all questions raised by this objection will be met, but in the sequence of the testimony it is impossible to cover the entire field at once.

Q. Does the presence of chlorine in the water of a river in the absence of the other chemical ingredients or constituents of sewage indicate of itself the presence of sewage pollution?

A. In my opinion the presence of chlorine under those conditions would be absolutely devoid of sanitary significance. It would be possible for a stream in the condition that the Illinois river was in at Kampsville, to be passed around the world several times in a closed conduit, consuming years or decades in the process, without altering materially the amount of chlorine in the water, although it is my judgment that, supposing the water were at the outset injurious to health, in the course of such a passage and in such a time, it would become entirely free from any injurious qualities it might have originally possessed.

Q. Professor, did you prepare any charts based upon the analytical tables for this period concerning which you have testified?

A. Yes, I have prepared five charts.

Q. How are the charts designated, professor, that you
9574 have prepared?

A. The first one "Chlorine, parts per million, in the Illinois river, Edwin O. Jordan."

Q. Was that chart prepared by you?

A. It was prepared under my supervision.

Q. From the tables and analytical data which have been offered in evidence?

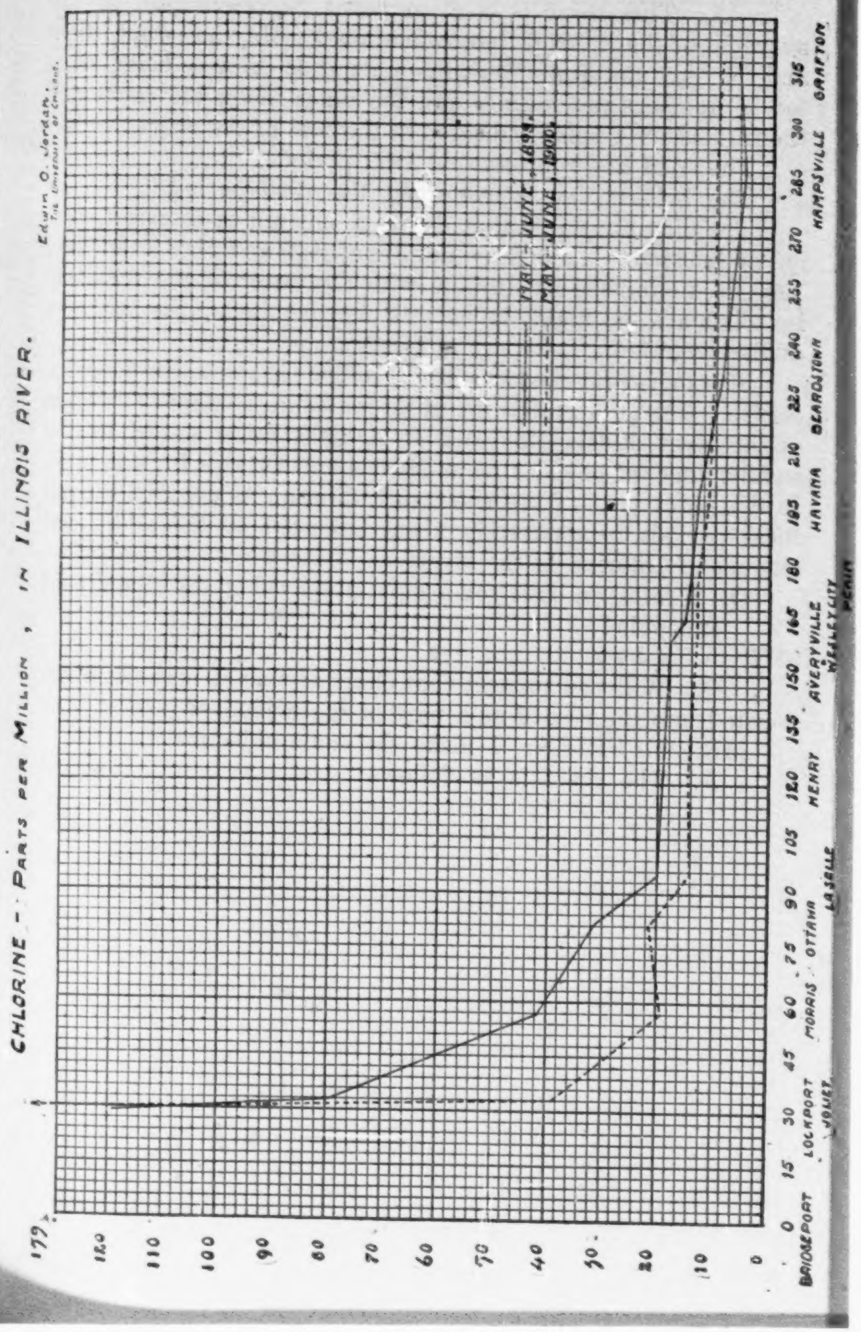
A. Yes sir.

Q. Will you present that chart so that it may be incorporated into the record as a part of the evidence?

MR. JEFFRIES: I object to the chart, to any of the charts which have just been referred to by the witness, being introduced in evidence for the same reasons stated in my objection to the introduction of the tables of analyses upon which the charts are based, or from which they were drawn.

A. The chart is as follows:

9575



CHLORINE - PARTS PER MILLION, IN ILLINOIS RIVER.
Edwin O. Jordan.
The University of Chicago.
MAY - JUNE, 1899.
MAY - JUNE, 1900.

9576 MR. TODD: Q. Will you please explain the chart?

A. This chart is a diagramatic representation of the averages of the chlorine detetrmination for May and June, 1899 and for May and June, 1900, the amount of chlorine being plotted in numbers per million and the miles along the course of the Illinois river being indicated at the foot of the chart.

The solid line representing 1899 period.

The broken line representing the 1900 period.

The diagram shows that the large amount of chlorine present at Lockport during May and June, 1899 and May and June, 1900, is diminished by dilution with the water of the tributaries which are less highly laden with chlorine during the progress of the river from Lockport to Grafton.

The curves for the two periods follow substantially the same course. The greater dilution of the water in the upper stretches of the river during May and June, 1900, being shown by the smaller amount of chlorine at Morris and Ottawa for example. In the lower part of the river such dilution as occured during these periods is apparently about balanced by the additional amount of chlorine in the river.

Q. Professor, have you a chart prepared on the albuminoid ammonia?

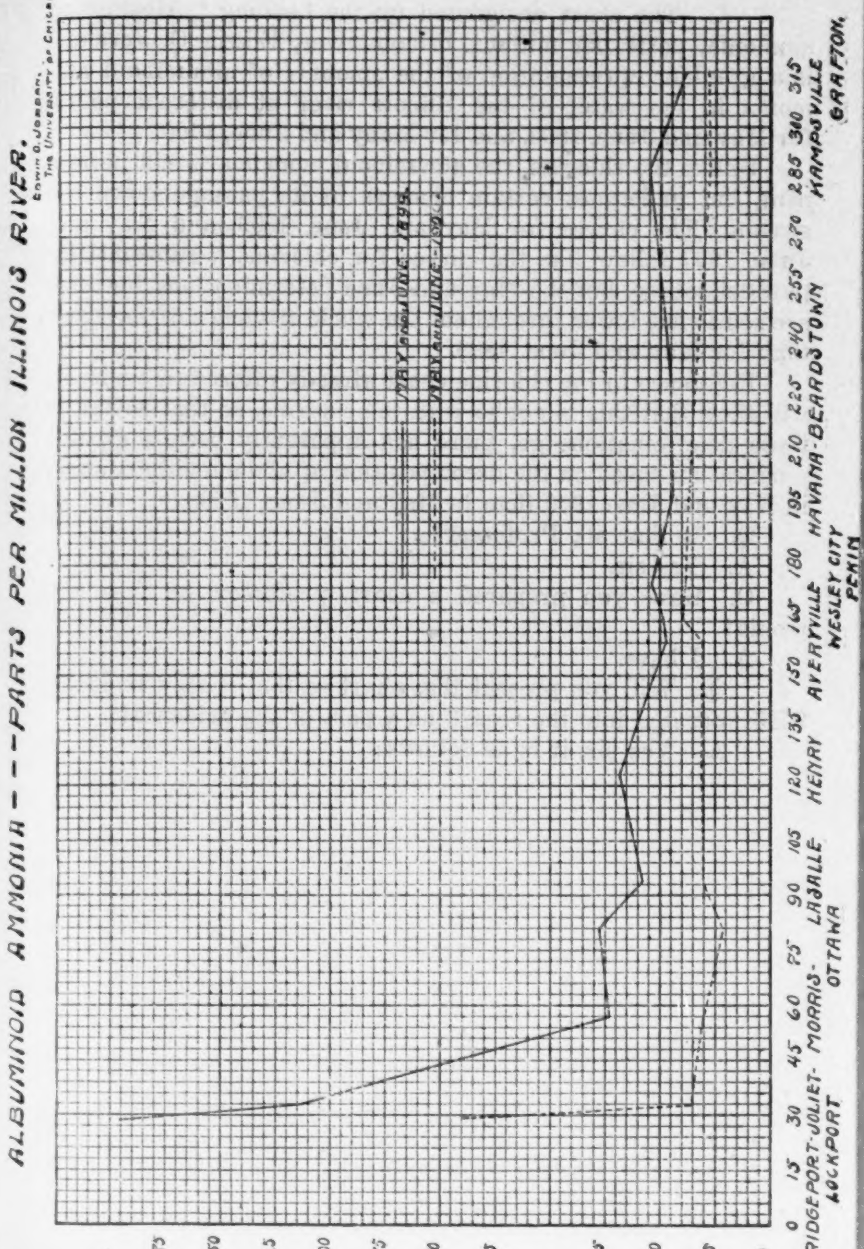
9577 A. I have.

Q. Will you present that chart so that it may be incorporated into the record as a part of the evidence?

MR. JEFFRIES: I make the same objection.

A. The chart is as follows:

9578



ALBUMINOID AMMONIA---PARTS PER MILLION ILLINOIS RIVER.
EDWIN O. JORDAN,
THE UNIVERSITY OF CHICAGO.

9579 Q. MR. TODD: Will you please explain the chart?

A. The chart designated by the heading "Albuminoid ammonia, parts per million, Illinois river, Edwin O. Jordan" is a graphic representation of the amounts of albuminoid ammonia in the water of the Illinois river at different points for May and June, 1899, and for Many and June, 1900.

Unlike the chlorine, the albuminoid ammonia is not permanent, but undergoes certain changes in its passage down the stream. The curves for May and June, 1899, and May and June, 1900 follow like the curves for chlorine, a substantially parallel course, but the May and June determinations for 1900 are somewhat lower throughout the whole stretches of the river than for May and June, 1899.

Reference to the chlorine chart already offered in evidence, will show that this is not so with the chlorine, so that so far as these determinations go, there has apparently been a greater purification based on the decomposition of albuminoid ammonia in May and June 1900 than in May and June, 1899.

Q. Is that all, Professor?

A. Yes sir.

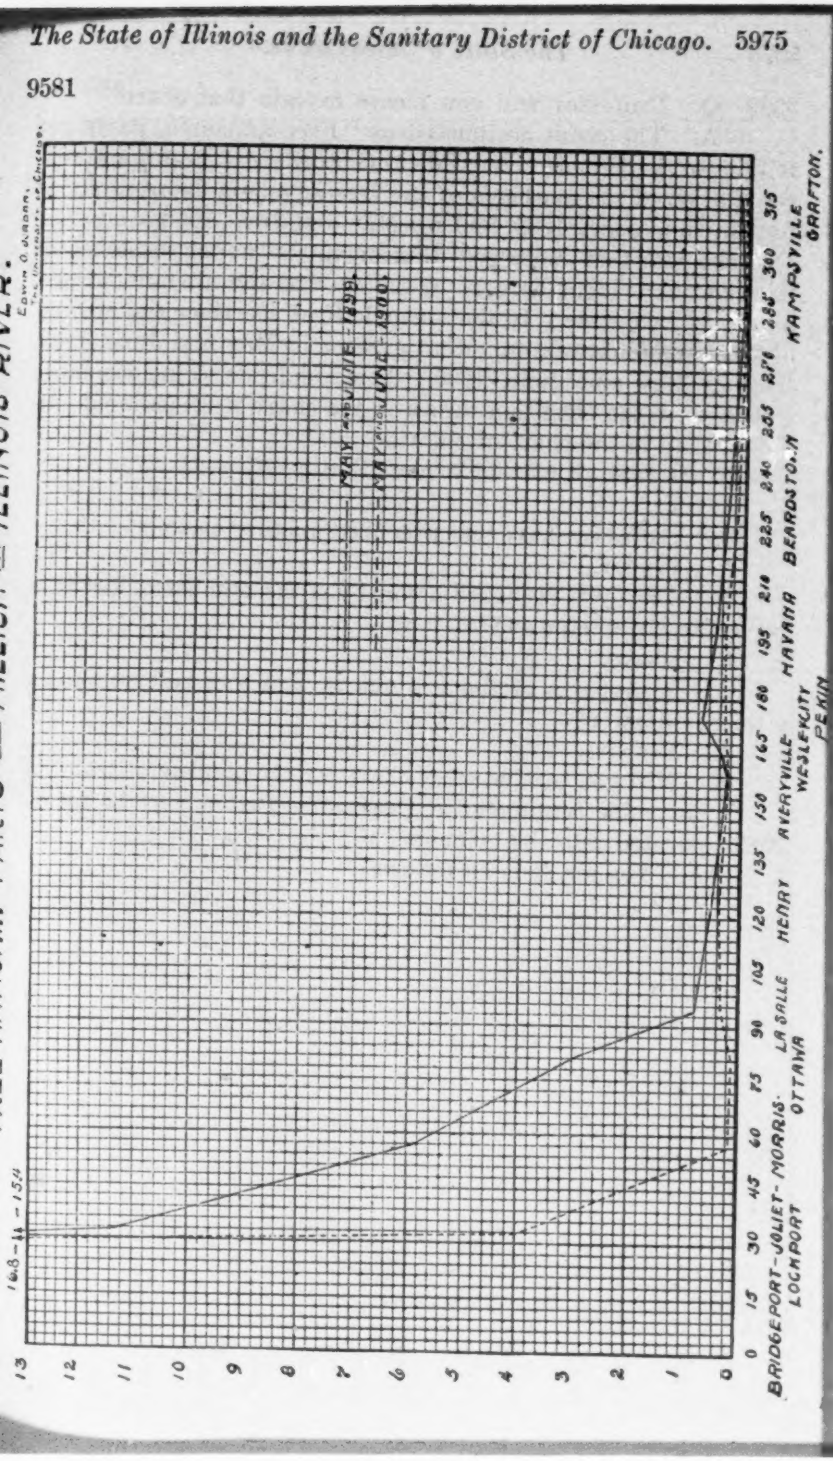
Q. Have you prepared a chart, professor, on free ammonia?

A. I have.

Q. Will you present that chart so that it may be incorporated into the record as a part of the evidence? 9580

A. Yes sir, it is as follows:

9581



RIVER.
EDWIN O. JORDAN,
THE UNIVERSITY OF CHICAGO.

9582 Q. Professor will you please explain that chart?

A. The chart designated as "Free ammonia, parts per million in the Illinois river, Edwin O. Jordan" is a graphic representation of the averages of the free ammonia determinations for May and June, 1899, and for May and June, 1900.

The effect of increased dilution in the upper stretches of the river is evident here as in the case of the albuminoid ammonia and chlorine. In the lower half of the river the amount of free ammonia was somewhat greater in May and June, 1899, than in May and June, 1900. This condition coincides more closely with the condition shown in the chart of albuminoid ammonia than in the chart of chlorine.

Q. Is that all of that explanation, professor?

A. Yes.

Q. Professor, have you prepared another chart?

A. Yes sir.

Q. Have you prepared a chart for the number of bacteria per cubic centimeter at Grafton?

A. I have.

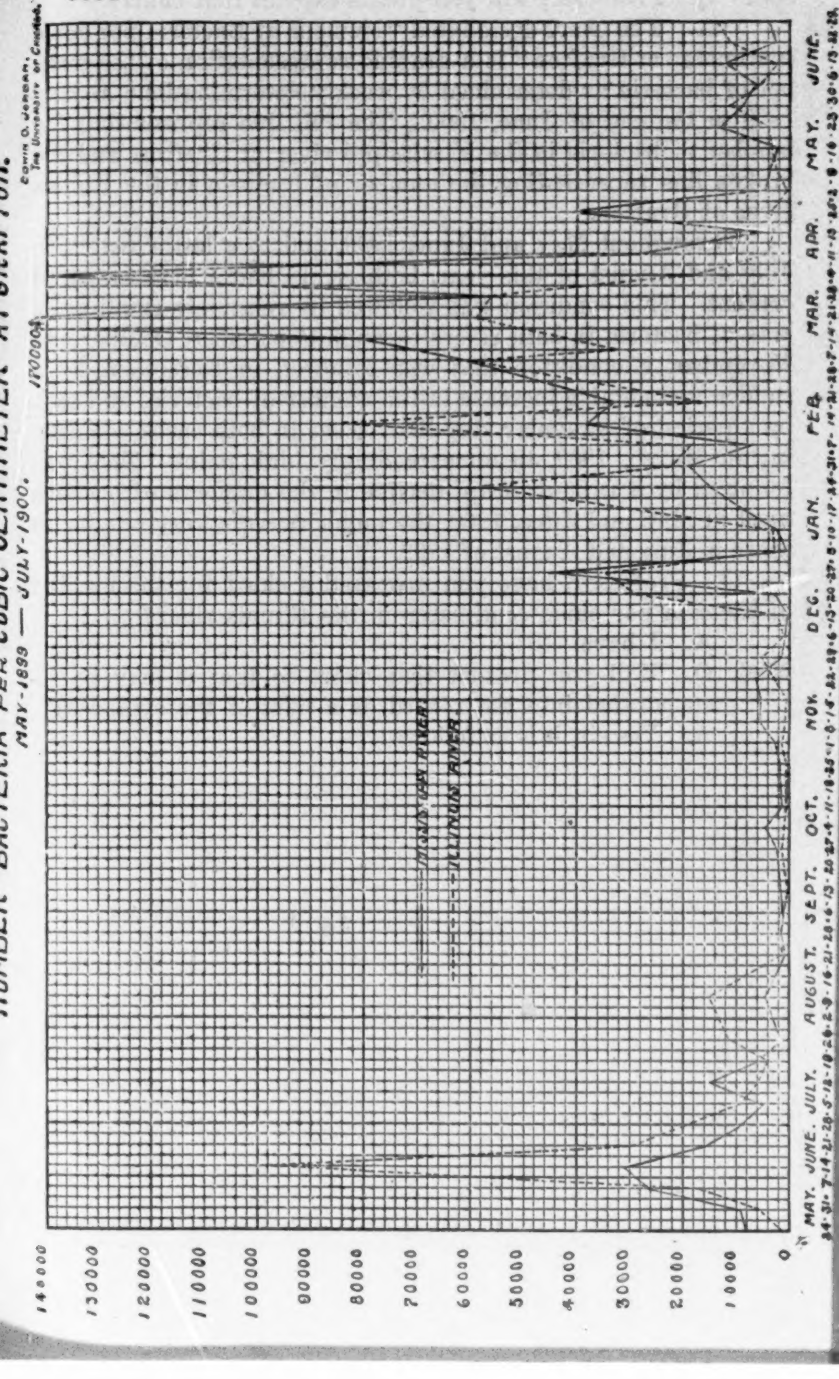
Q. Is that one of the five charts that you referred to in a former answer?

A. Yes sir.

Q. Will you produce that chart for the number of bacteria per cubic centimeter at Grafton so that it may be incorporated into the evidence? 9583

A. Yes sir, it is as follows:

9584



BACTERIA PER CUBIC CENTIMETER AT GRAFTON.

MAY. JUNE. JULY. AUGUST. SEPT. OCT. NOV. DEC. JAN. FEB. MAR. APR. MAY. JUNE.

9585 Q. Professor, will you please explain that chart?

A. The chart designated "Number of Bacteria per cubic centimeter at Grafton" is a graphic representation of the number of bacteria as determined by weekly determinations in May 1899 to the end of June, 1900. The full line representing the number of bacteria in the Mississippi river at Grafton, and the broken line representing the number of bacteria in the Illinois river at Grafton.

Throughout May and June, 1899, and to a lesser extent in July and August of this year, both rivers had a high bacterial content. This condition was followed by relatively small numbers of bacteria in both rivers through September, October and November, a condition that was followed in December, by a sudden and notable increase in the number of bacteria, and then by a period of irregular step-like ascent in both cases, amounting in March, 1900, to an exceedingly high point. This was followed by a rather abrupt decline in the numbers of bacteria until in May and June, 1900, the numbers were very similar to those in July and August of 1899.

Q. Professor, have you prepared a chart for the number of bacteria per cubic centimeter in the Illinois river?

A. I have.

9586 Q. Will you present that chart so that it may be incorporated into the record as a part of the evidence?

A. Yes sir, it is as follows:

9587

MAY AND JUNE - 1899.
MAY AND JUNE - 1902.

9588 Q. Professor, please explain that chart?

A. The diagram designated "Number of bacteria per cubic centimeter in the Illinois river, Edwin O. Jordan" is a graphic representation of the average numbers of bacteria for May and June of 1899, and May and June, 1900, starting at Lockport with high initial numbers in both cases.

The number of bacteria drops to a relatively low point in the neighborhood of Ottawa, continuing low to Averyville, below that point, showing a very notable increase, especially during the first period, apparently due to the pollution of Peoria. As with the initial pollution the numbers of bacteria introduced at Peoria diminish, and for the last stretch of 120 miles the numbers of bacteria are very similar to those found at Henry and Averyville above Peoria.

The increase in numbers of bacteria at Wesley City below Peoria is apparently much less in May and June, 1900 than in May and June, 1899. This however is probably apparent rather than real and is due to the fact that the sample which was collected in mid-stream at Wesley City, did not give as definite indication of the addition of Peoria sewage as was the case in the 1899 period, since the greater body of water in the Illinois river at this time probably crowded the pollution towards the western bank.

ADJOURNED until 10:00 A. M. following day, Wednesday, December 2nd, 1903.

9589 10:00 A. M., Wednesday, December 2nd, 1903. Continuation pursuant to adjournment.

Present, the Commissioner and same counsel representing the respective parties.

PROF. EDWIN O. JORDAN,

resumed the stand for further direct-examination by Mr. Todd and testified as follows:

Q. Professor, referring to the five diagrams presented by you in evidence yesterday, what was the signification of the numbers at the bottom of the diagrams?

A. The numbers at the bottom of the diagrams headed "Chlorine, parts per Million, in the Illinois river;" "Albuminoid ammonia, parts per million, in the Illinois river;" "Free ammonia, parts per million in the Illinois river," and "Number of Bacteria per cubic centimeter in the Illinois river" refer to the distance in miles from Bridgeport as a starting point, the approximate position of the collecting stations being given below the figures. Thus, the distances from Bridgeport in miles, are as follows:

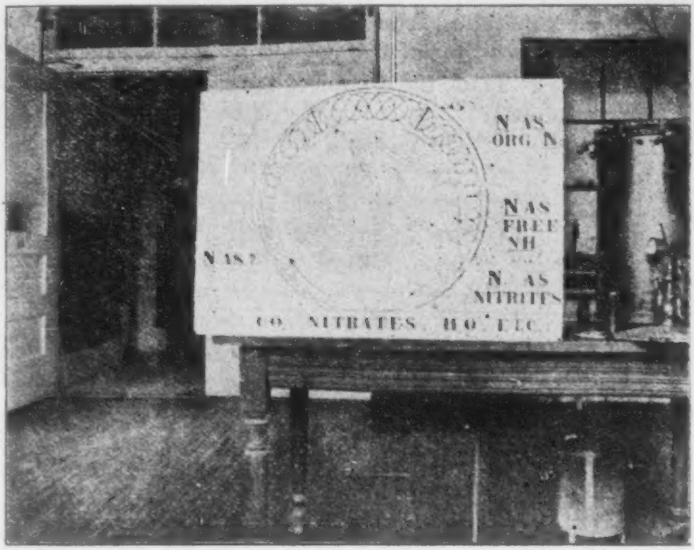
9590	Lockport,	29 miles,
	Joliet,	33
	Morris,	57
	Ottawa,	81
	LaSalle,	95
	Henry,	123
	Averyville,	159
	Wesley City,	165
	Pekin,	175
	Havana,	199
	Beardstown,	231
	Kampsville,	288
	Grafton,	318

Q. Have you any further explanation to give regarding the significance of the four kinds of nitrogen compounds determined in sanitary water analyses?

A. I have here a photograph of a diagram which I would like to explain.

MR. TODD: I offer the photograph as a part of the evidence; it is as follows:

9591



9592 Q. Please read the above question to the witness.

(Question read as follows:)

Have you any further explanation to give regarding the significance of the four kinds of nitrogen compounds determined in sanitary water analyses?

A. This is a photograph of a schematic representation prepared by Professor Sedgwick and myself some fifteen years ago. It is intended to illustrate the various stages in the decomposition and oxidation of nitrogenous organic matter. The circle represents what may be termed the cycle of nitrogen in its relations to the living world. In the upper part of the diagram the large spirals indicate the relative complexity of the organic nitrogenous substances forming the bodies of plants and animals, and excreted from them as waste products. Nitrogen in this stage appears in the analytical tables as so much organic nitrogen or albuminoid ammonia. By the agency of bacteria and other micro-organisms this nitrogenous organic matter is broken down into less complex compounds, the nitrogen in this stage being designated on this chart as nitrogen as free ammonia.

An attempt is made to indicate the less complex condition of these nitrogenous bodies by smaller and less
9593 intricate spirals. The oxidation of the free ammonia to
nitrites is the next step in the process of oxidation, the nitrites being in turn oxidized to the completely mineralized nitrates, which with carbon dioxide, water and other substances devoid of available potential energy, occupy the region of complete mineralization at the bottom of the circle.

Various forms of plant life are able with the aid of sunlight to utilize the nitrogen of the nitrates as food; and through stages of ever increasing complexity, the exact nature of which is unknown, the nitrates are built up again, into the living bodies of plants and animals, and become again organic nitrogen, from which point the nitrogen eventually starts anew on its cycle.

Owing to the effect that the occurrence of nitrogen in the form of organic nitrogen and as free ammonia is associated with the decomposition of substances discharged from the bodies of animals, the presence of nitrogen in these forms indicates relatively recent contamination with organic matters, while owing to the time that must elapse for the process of nitrification to be completed, the occurrence of nitrates in inconsiderable abundance in surface water is taken as indicating that a relatively long period has elapsed since original contamina-
9594 tion took place.

In such a water as the Illinois river, the nitrogenous matter introduced in the Chicago sewage may pass through this complete cycle several times on its way to the mouth of the river. The oxidation of the organic nitrogenous compounds introduced into the river at Lockport may take place under certain circumstances in the upper stretches of the river. The nitrates thus formed may be utilized by microscopic algae for building up their life substances, and thus again pass into the state known as organic nitrogen or albuminoid ammonia. From the advent of cold weather, or from other unfavorable circumstances these organisms may die, and the nitrogen composing their bodies being again decomposed, may reach the mineralized form of nitrate and perhaps again begin the upward part of the cycle.

Under certain circumstances, any river into which an excessive amount of nitrogenous matter is emptied, will contain throughout a large part of its course, an amount of nitrogen in one form or another, in excess of that existing in a stream not so laden at the start. Under such conditions the appearance and reappearance of nitrogen as free ammonia, albuminoid ammonia, or one or another of these compounds, cannot be held to possess the same sanitary significance as under
9595 some other conditions.

Free ammonia at the mouth of the Illinois river for example, may be derived from a decomposition of algae, while free ammonia at Lockport or Bridgeport may be derived from decomposition of waste substances leaving the human or animal body, or discharged into the water in the course of various manufacturing operations.

This diagram I think, serves to illustrate some of these points and to show the complexity of the phenomena attending the decomposition of organic compounds containing nitrogen, and the re-composition of this nitrogen in the bodies of other living forms.

Q. Did you make any hourly bacteriological survey of the water of the Illinois river below Morris?

A. Yes sir.

Q. Please state when this survey was made and describe it in detail?

A. I have made such examinations of the river between Morris and Ottawa, at Wesley City, and at Grafton.

Taking first the determinations made on the Illinois river at Morris. Several series of observations were carried out at this point. The first of these was on October 7th, 1899.
9596 The day was bright and sunny, the temperature of the air being 7 degrees centigrade at six o'clock in the morning, and reaching 20.5 by mid-day. A slight breeze ruffled the surface of the water in the middle of the day, but was at no time strong. The river was very low, the gauge reading for that day being five feet, and the current exceedingly sluggish.

With a view to determining the distribution of bacteria in different portions of the Illinois river at this point, a cross-section was taken across the river from the right to the left bank; three samples being taken at approximately equi-distant intervals from one another and from the shores. The upper cross sections were taken at a point just above the Mazon river, the lower about three-quarters of a mile below the mouth of the Waupecan Creek. This was at a dry period, and little if any water passed into the Illinois from these tributaries at this date. This stretch of river is almost exactly three miles in length. The rate of flow between the two points was determined by weighted floats and by the use of fluorescein solution, and was found to be very close to half a mile per hour.

Four series of cross sections at hourly intervals were taken
at the upper station, which may be designated as Sta-
9597 tion A, and these were followed by a similar series at
the lower station, Station B, beginning six hours later.
These samples were plated immediately after collection, the plating being completed within the hour in each case.

At Station A the river was about 150 yards wide, and at Station B about 125.

The figures given for the number of colonies in the tables that follow are the averages of counts of two separate platings.

9598

UPPER STATION (A).

Hour.		No. Colonies per cc.	Turbidity (Hazen's scale).	Temp. Water °C.	Chlorine (parts per million)
6:15 a. m.	Right Bank	500,000	.16	13.	....
"	Center	378,000	.12	13.	....
"	Left Bank	42,000	.075	13.	....
7:15 a. m.	Right Bank	368,000	.17	13.	....
"	Center	344,000	.125	13.	....
"	Left Bank	35,000	.0775	13.	....
8:15 a. m.	Right Bank	752,000	.16	13.5	91
"	Center	364,000	.11	13.	69
"	Left Bank	30,000	.0675	13.	45
9:15 a. m.	Right Bank	554,000	.16	14.	....
"	Center	472,000	.11	14.	....
"	Left Bank	79,000	.075	14.	....

LOWER STATION (B).

(Three miles below A).

Hour.		No. Colonies per cc.	Turbidity (Hazen's scale).	Temp. Water °C.	Chlorine (parts per million)
12:15 p. m.	Right Bank	480,000	.13	16.	....
"	Center	327,000	.15	16.	....
"	Left Bank	87,000	.05	16.5	....
1:15 p. m.	Right Bank	281,000	.1475	16.	....
"	Center	102,000	.09	16.	....
"	Left Bank	19,000	.042	16.	....
2.15 p. m.	Right Bank	400,000	.13	17.	87
"	Center	249,000	.09	16.	72
"	Left Bank	22,000	.045	16.	52
3:15 p. m.	Right Bank	412,000	.136	17.	82
"	Center	416,000	.12	16.	78
"	Left Bank	11,000	.0433	17.	53

9599 The averages may be tabulated as follows:

		No. Colonies per c. c.			No. of Hourly
	Distance.	Right Bank.	Center.	Left Bank.	Analyses.
Upper Station (A).....	......	543,700	389,700	46,500	4
Lower Station (B).....	3 miles (6hours).	393,250	273,500	34,750	4
Percentage Decrease		27.6	29.8	25.3	

9600 Attention may be directed to the fact that between these collecting stations, a distance of three miles travelled by the stream on this date in about six hours, a great bacterial diminution occurs. The chlorine determinations show that the mixing of the Kankakee water and the Desplaines water is very incomplete both at the upper station which is about nine and one-half miles below the junction of the rivers, and at the lower station as well. This is entirely confirmed by the bacterial count and turbidity cross sections at the two points.

It should be noted that the decline in the numbers of bacteria occurs in almost equal degree throughout the whole breadth of the stream, being as great along the highly polluted right bank of the river as along the comparatively uncontaminated left bank.

A second series of observations was carried out on November 9th, 10th, and 11th, 1899, in similar fashion, upon a longer stretch of river. The distance between the regular collecting station at Morris and the regular collecting station at Ottawa is about 24 miles, and the rate of flow between these points averaged one-half a mile per hour at the time our observations were made. A point midway between Morris and Ottawa was selected, near Seneca, and a three days' series of operations was planned.

9601 The sun was wholly obscured by clouds during these three days, but no rain fell. The results are given as before, in tabular form, as follows:

9602

UPPER STATION (MORRIS).

Hour.	No. Colonies per cc.	Turbidity (Hazen's scale).	Temp. Water °C.	Chlorine (parts per million)
7:15 a. m. Right Bank	433,000	.153	7.	....

" " Center	52,000	....	11.	....
" " Left Bank	52,000	....	11.	....

*Turbidity readings could not be taken accurately at this point and at Ottawa owing to presence of water weeds.

LOWER STATION (OTTAWA).

Hour.	No. Colonies per c. c.	Turbidity (Hazen's scale).	Temp. Water °C	Chlorine (parts per million).
10:00 a. m., Nov. 11. Right Bank	11,000	Less than .04	9.5	49
" " Center	10,500		9.5	46
" " Left Bank	3,900		9.5	43
1:00 p. m, Nov. 11. Right Bank	12,000	....	9.5	....
" " Center	11,000	....	9.5	....
" " Left Bank	18,000	....	9.5	....

The averages are as follows:

	Distance from Morris.	No. Colonies per c. c. Right Bank.	Center.	Left Bank.	No. of Hourly Analyses.
Upper Station (Morris).....	......	261,000	204,000	29,000	3
Middle Station (Seneca)....	12 miles. 24 hours.	100,000	49,000	35,000	2
Lower Station (Ottawa)....	24 miles. 48 hours.	11,500	10,700	13,500	2

9603 During this flow of 24 miles therefore, the Illinois river became nearly free from the great mass of sewage bacteria with which it was originally laden. In fact the bacterial content of the Illinois at Ottawa on this date was not greatly in excess of that of the local tributary streams.

In connection with this series of bacterial determinations may be given the averages of the regular chemical determinations made at the laboratory in Chicago during the period between October 23rd and November 20th, 1899. These determinations, which follow, show that a considerable degree of nitrification takes place in the river between these two points, as witnessed by the increase in the amount of nitrites and nitrates, the diminution in free and especially in the albuminoid ammonia.

9604

Station.	No. Determinations.	Residue on Evaporation. Total.	Dissolved.	Suspended.	Oxygen Consumed. Total.	By Dissolved Matter.	By Suspended Matter.
Morris	5	398	380	18.	10.7	8.4	2.3
Ottawa ...	5	356	353.5	2.5	7.5	7.3	.2

Nitrogen as Free Ammonia.	Albuminoid Ammonia. Total.	Dissolved.	Suspended.	Nitrites.	Nitrates.
7.98	.860	.478	.382	.028	.340
6.6	.364	.315	.049	.382	.648

9605 A third series of similar observations was made between these same points on May 24th, 25th and 26th, 1900. The sun was partially obscured on May 25th, but shone brightly on May 24th and 26th. No precipitation occurred during the period.

The results follow as before, in tabular form:

9606

UPPER STATION (MORRIS).

Hours.		No. Colonies per c. c.	Temp. Water °C.	Chlorine. (Parts per million).
7:30 a. m., May 24.	Right Bank	45,000	15.5	20

Middle Station (Seneca)..	12 miles.	9,100	9,100	10,300	4
Lower Station (Ottava)..	24 miles.	8,200	7,700	6,300	3

9607 This last series of determinations shows that on May 24th, 25th and 26th, 1900, the mixing of the Kankakee and Desplaines rivers at Morris was more complete than on November 9th, 10th, and 11th, 1899. They also show a smaller number of bacteria per cubic centimeter of the water at this time. A diminution in the number of bacteria, however, similar to that noted in the earlier series takes place during the flow from Morris to Ottawa, and there are fewer bacteria per cubic centimeter as shown by the colony count at Ottawa during this period in 1900, than in November, 1899.

I see no escape from the conclusion that in this flow of approximately 24 miles, the Illinois river which at Morris contained a large number of bacteria in all probability derived more or less directly from the sewers of Chicago freed itself from these bacteria to a remarkable and impressive degree in a short distance and in a relatively short space of time. The probable reason for the high mortality among bacteria in this particular stretch of the river will be discussed in another connection.

I should like to state that these three series of observations upon the water of the Illinois river between Morris and Ottawa are not the only series that I have made between
9608 May 1899 and June, 1900.

Q. What other observations have you made professor?

A. I have made several other series of observations between Morris and Ottawa of the same character as those just described. The samples were collected in the same way, the experiments in each case being conducted by my chief assistant, Mr. Irons, and myself.

Q. When were the subsequent experiments made?

A. Between July, 1899 and June, 1900.

Q. That is between Morris and Ottawa?

A. Between Morris and Ottawa.

Q. Can you give the dates?

A. One of these was on September 2nd, 1899. I have memoranda of the others with my papers at the University.

Q. Professor, will you describe how these samples were taken from which the foregoing analyses that have been introduced in evidence were made, and the conclusions drawn?

A. These samples were taken from a row-boat. The floats and flourescein introduced into the water were followed down stream in the boat, so that it was possible to determine very closely the passage of a given body of water from one point to another, the object of the experiment being to observe the changes in one and the same mass of water flowing from
9609 point to point. This was true of the collections of water samples made immediately below Morris; the collections made at Seneca and at Ottawa were also made from a boat at regular intervals, but the entire body of water was not fol-

lowed the whole distance from Morris by boat, the approximate time necessary for the passage of the water from Morris to Seneca, and from Seneca to Ottawa being determined and hourly examinations made at the lower points.

Q. Professor, did you make any cross section experiments at Wesley City?

A. Yes sir. On several occasions cross sections were taken at Wesley City below Peoria to determine the amount of mixing at this point.

Q. When were these experiments made?

A. One of these, of which I have a record here, was made on June 13th, 1900. It gave the following result:

	Free ammonia.	Albuminoid ammonia.	No. of colonies per c. c.
Right bank,	.504	.864	4,340,000
Center,	.144	.248	40,000
Left bank,	.168	.240	2,400

This cross section was not made by me personally, but by Mr. Irons, in pursuance of my directions.

9610 The large amount of pollution entering the river at Peoria on the right bank of the river is clearly shown in this sample. The free ammonia, the albuminoid ammonia, and the number of bacteria per cubic centimeter being immensely greater than on the left bank of the stream. Slight changes in the position of sand-bars and in the height of water deflect the main mass of pollution now to one side, of the stream, now to the other, and so lead to the sudden and marked fluctuations in the analyses which the detailed tables show to be so characteristic of the samples obtained from this point.

Q. Did you make a cross section investigation at Grafton?

A. Yes, on a number of occasions both in 1899 and in 1900, cross-sections were taken of the Illinois river at Grafton. These cross-sections at Grafton dealt simply with the number of bacteria per cubic centimeter. In general it may be said that the results obtained from samples taken midway between the banks of the streams and the center were not materially different from those taken from the center of the stream, mixing of the bacteria, so far as these determinations go, being complete at this point. Slight variations were however, sometimes noticed, the number being sometimes higher in the center than on the sides; sometimes higher on the sides than in the center.

Q. What sanitary significance do you attach to the experiments conducted by you at Morris which have been testi-
9611 fied to by you in evidence?

A. These observations upon the bacterial content of the Illinois river between Morris and Ottawa indicate in my judgment that a very large proportion of the bacteria entering the Desplaines river from the Illinois and Michigan canal and from the Chicago drainage canal do not survive to reach Ottawa. From a sanitary point of view this observation would seem to be of importance in that it renders less probable the passage of disease germs down the river, as far as this point. Since these sewage bacteria disappear in such numbers, it is in my opinion, fair to assume that the various non-spore forming pathogenic bacteria entering the Chicago sewage, die out at least in the same proportion.

MR. JEFFRIES: The opinion of the witness being based solely upon the result of the last experiment just detailed in evidence, I move to strike it out for the reason that the analyses so made were so limited that no reliable conclusions can be drawn therefrom, which would cover all periods, conditions and circumstances, surrounding the Illinois river at the point in question, and characterizing the sanitary condition of that water during the various periods, and at maximum and minimum conditions of pollution and infection, as well as the temperature of the water and the atmosphere at all times.

9612 Q. MR. TODD: In giving the latter part of your opinion, have you taken into account any other knowledge that you possess except the knowledge gained from this experiment?

MR. JEFFRIES: I object to the question for the reason that the witness' opinion is based upon the preceding question and had reference solely to the result of the bacterial analyses of that water and the question just asked the witness partakes of the nature of a question in cross-examination. It is therefore incompetent and improper.

Q. (Question repeated):

A. In giving the last opinion I am of course obliged to take into consideration all the knowledge that I possess on the life of pathogenic germs and their relation to sewage bacteria. I regard however, these observations upon the bacterial content of one and the same body of water as re-inforcing in a remarkable manner all that I have been able to learn in other ways regarding the life of bacteria introduced into water with sewage.

Q. Did you make any determinations for the bacillus coli communis?

A. Yes sir, I did.

9613 Q. Covering what period of time?

A. I have made several series, the first covering the period between May, 1899 and June, 1900.

Q. At what points were these determinations made?

A. These were made upon samples of water collected from the Illinois and Michigan canal at Lockport.

From the drainage canal at Kedzie Avenue.
From the drainage canal at Lockport,
From the Desplaines river at Lockport.
From the Kankakee river at Wilmington.
From the Illinois river at Morris.
From the Fox river at Ottawa.
From the Illinois river at Ottawa.
From the Big Vermillion river at LaSalle.
From the Illinois river at LaSalle.
From the Illinois river at Henry.
From the Illinois river at Averyville.
From the Illinois river at Wesley City.
From the Illinois river at Havana.
From the Sangamon river at Chanderville.
From the Illinois river at Grafton.
From the Mississippi river at Grafton.
9614 From the Mississippi river at Alton, a cross-section.
From the Missouri river at West Alton.
From the Mississippi river at intake tower of St. Louis waterworks.
St. Louis tap water.

Q. Were these examinations made from the same samples sent by the same water takers from these different places as heretofore testified by you in evidence

A. Yes sir; in the tables containing the results of these determinations, this fact is indicated by the serial number accompanying each determination.

9615 Q. Have you a list of tables prepared showing bacillus coli communis determinations?

A. I have.

Q. Were these tables prepared in the same manner as the other tables which you have testified to as to the chemical and bacterial analyses that have been introduced?

A. They were.

Q. Will you give the characteristics of the bacillus coli communis?

A. The bacillus coli communis, or the colon bacillus is, as its name implies, a bacterium inhabiting in large numbers that portion of the alimentary tract known as the colon. It is the bacillus commonly found in this situation.

The colon bacillus grows readily upon the ordinary culture media used in the bacteriological laboratory, in beef tea, upon nutrient beef jelly, made with gelatin and agar; upon potato and in milk. On all these food substances it thrives luxuriantly, producing in many cases characteristic growth effects and chemical changes.

The colon bacillus is one of the rod-shaped bacteria and is sluggishly motile. It is not known to form spores.

Q. Where else in nature is this bacillus coli communis found, except in the colon in man?

9616 A. It is found in the intestinal discharges not only from man, but from many other of the higher animals; it is found also in waters and soils contaminated with animal excreta. It is found sometimes in the dust of streets. Its occurrence in this situation being probably due to the presence of horse droppings. It is sometimes, though but rarely, found in the air, in pure water and in the deeper layers of soil it is found if at all, in very small numbers.

Q. What is the relationship of the bacillus coli communis to the bacillus typhosus?

A. The colon bacillus is exceedingly similar to the typhoid bacillus in many of its morphological and biological characters,

In shape, size, motility, lack of spore formation, it resembles the typhoid bacillus so closely that the most experienced bacteriologists have difficulty in distinguishing between these two organisms on the basis of the characters just enumerated. The growth of these two organisms upon beef broth and gelatin agar, is again so similar that by these characters alone it is not possible to distinguish between the two microbes. The typhoid bacillus and the colon bacillus in fact, belong to a group of bacteria, including a large number of bacteria both pathogenic and
9617 non-pathogenic. The different members of this group, which is known among bacteriologists as the colon typhoid group, differ from one another by relatively slight biological peculiarities. While the typhoid bacillus and the colon bacillus are thus intimately related, there are, nevertheless certain constant characteristics which enable an experienced observer to distinguish between the two forms. Some of the main points of difference are, that the colon bacillus is able to ferment dextrose with gas production, while the typhoid bacillus, although producing acid from dextrose, is not known under any circumstances to produce gas; when grown in milk the colon bacillus produces acid from the milk sugar, curdling the milk. The typhoid bacillus is not able to do this.

These are some of the fundamental distinctions between these two germs. The colon bacillus is in every respect more hardy than its near relation the bacillus typhosus.

In comparative tests that have been made on the relative viability of the bacillus coli, and the bacillus typhosus under certain conditions, the following facts have been demonstrated:

1. As regards sand filtration with the water to which both species have been added, 99.9 per cent of all the bacillus
9618 coli and 100 per cent of the bacillus typhosus were removed by an intermittant filter, and 99.8 per cent of bacillus coli and 99.9 per cent of bacillus typhosus by a continuous filter.

2. As regards the persistence of the two organisms in a filter after infection of the applied water has ceased, bacillus coli was found to continue in the effluent from the intermittent filter for 24 to 36 hours, and the bacillus typhosus only for two to three hours. With the continuous filter the bacillus coli

continued for forty-six days, and the bacillus typhosus for two days.

3. The effect of cold without freezing. In a water subjected to a temperature of 33 degrees Fahrenheit, about 90 to 95 per cent of both species were destroyed within 24 hours. A few organisms of each, however, may live for a considerable number of days.

4. Elimination by freezing and viability in ice. About 50 per cent of the bacillus coli and 75 per cent of the bacillus typhosus, were destroyed by fifteen minutes freezing, after one hour, 95 per cent of the bacillus coli and 98 per cent of the bacillus typhosus were killed, and at the end of 24 hours over 99 per cent of all the organisms had disappeared.

5. Resistance to heat. Both species resisted temperatures
9619 up to 45 degrees for five minutes. And between 45 and
55 degrees centigrade, all but a few individuals of each are destroyed. These few individuals however, resisting temperature up to 85 degrees centigrade, at which temperature all organisms of both species were destroyed.

As bearing further on the question of the relative resistance of these two organisms I may state that some experiments were made by me some years ago a report of which is printed in the Medical News on September 28th, 1895, in which it was found that the typhoid bacillus when introduced into sterilized Lake Michigan water, does not multiply, but may under certain conditions, maintain its vitality for upwards of 93 days. The colon bacillus on the contrary, under the same conditions, undergoes rapid multiplication and may remain alive for upward of 263 days.

ADJOURNED until 2:00 P. M. same day, Wednesday, December 2nd, 1903.

RECORD

vs.

The State of Illinois

and

Sanitary District of Chicago

VOL. 7

1272
S.6.

IN THE

Supreme Court of the United States

THE STATE OF MISSOURI
vs.
THE STATE OF ILLINOIS
and
THE SANITARY DISTRICT OF CHICAGO.

Original,
Docket No.

Before
FRANK S. BRIGHT,
Commissioner of the Supreme Court of the United States.

VOLUME 7.

A–375a

VOLUME 7.

2:00 P. M., Wednesday, December 2nd, 1903.

9620 Continuation pursuant to adjournment.

Present, the Commissioner and same counsel representing the respective parties.

PROF. EDWIN O. JORDAN,

resumed the stand for further direct-examination by Mr. Todd and testified as follows:

(Witness continues answer begun before adjournment).

From the facts just enumerated, it is clear that while the colon bacillus resembles in many important particulars the typhoid bacillus, it is under all conditions in which the viability of these two organisms has been compared a more hardy and more resistant organism. Its longevity under adverse conditions is greater than that of the typhoid bacillus. This fact, and the ease with which it is isolated and identified, combine to render it a particularly significant organism from a sanitary point of view.

Q. What is the significance of the bacillus coli communis in sanitary water analyses?

A. Owing to the fact that bacillus coli communis leaves 9621 the human body in large numbers in feces, it is one of the prevailing forms in fresh sewage. For this reason the presence and relative abundance of bacillus coli communis in water is regarded as one of the most delicate, precise and altogether significant indications of recent sewage pollution.

As an illustration of the way in which the presence of this organism can be used for demonstrating the existence of pollution of a dangerous character, I may cite from a paper upon Municipal Water Supplies, and Their Examination, by Dr. William G. Bissell, of Buffalo, New York, bacteriologist of the

Department of Health in Buffalo. This paper was printed in the Philadelphia Medical Journal August 30th, 1902.

"Two samples were prepared, each representing one-half gallon of water, one was a sample of water from the Niagra river taken from the tap at Buffalo after it had passed through a sterilized filtering stone of a Pasteur Chamberland filter. To this sample there was added a small proportion of salt. The other was a sample of Niagra river water collected at Niagra Falls (and in which it was easy to demonstrate the colon bacillus in cubic centimeter amounts of the sample) into which there was introduced a small aount of human excreta. No data were sent with either sample, except that they were said to
9622 be river water." " 'Reports came back that the source from which the first sample was obtained was 'unsafe for use on account of the high percentages of chlorides" and that the second sample was 'wholesome for household use.'''

This illustration suffices to show that it is possible by means of the delicate test for colon bacilli to detect a degree of pollution which might be altogether missed by the use of less delicate and less precise methods.

So far as I have been able to discover, it is at the present time, the prevailing opinion among those bacteriologists who deal with sanitary water analysis that the test for the colon bacillus properly applied and interpreted, furnishes one of the most satisfactory clews to the sanitary condition of a water.

In this connection it should be emphasized that it is not so much the presence or absence of bacillus coli communis in a large quantity of water that is significant as it is the relative abundance of this micro-organism.

I will cite a statement from a recent monograph bearing upon this matter. This monograph is by Dr. William G. Savage, lecturer on bacteriology, University College, Cardiff, Wales; bacteriologist to the Cardiff County Public Health Labora-
9623 tory. The article is entitled: "The Significance of the bacillus coli in drinking water." and appeared in the Journal of Hygiene, 1902, Volume 2, page 320, edited by Professor George H. F. Nuttall, and published by the Cambridge University Press. This author gives extended tables of the examinations of waters from various sources for their content in colon bacilli.

On page 321, the author states that

"In such an investigation the three following points must in my opinion always be kept in view:

1. That it is not so much the presence of B. coli which is of possible value but the number present. The consideration of the problem is essentially quantitative, and the number of B. coli in a standard amount of water must be considered. This view is insisted upon by many English bacteriologists, and there can be no doubt of its vital importance in studying the question."

In his conclusions on page 338, the writer states that

"The number of B. coli present is an essential factor but arbitrary standards of the number of this organism allowable per liter, are of but little value, and are fraught with considerable possibilities of error, unless the particular kind
9624 of water and the local conditions are considered in every case."

In further support of the view already expressed as to the significance of bacillus coli in water supplies, I may cite a report of a committee of the American Public Health Association presented at the Washington meeting of this association October 26th to 30th, 1903. An abstract of this report being printed in the Journal of the American Medical Association for November 21st, 1903, page 1292.

This report of the committee on the significance of bacillus coli in water supplies was presented by the Chairman, Professr S. C. Prescott, Assistant Professor of Biology at the Massachusetts Institute of Technology. The abstract is in part as follows:

"To present a statement of the opinion of the committee individually and as a whole, as probably representing the generally accepted views of sanitary bacteriologists as to the significance of B. coli in water, the following questions were sent to each member; the answers appended, except as otherwise stated, were practically as given below:

1. In view of the fact that numerous investigators have found B. coli in nature where it could not be directly traced to sewage or fecal pollution, do you believe that the colon
9625 test of water is as safe an index of pollution as it was formerly regarded to be?

Yes sir.

2. Are you of the opinion that the number of colon bacilli rather than their presence, should be used as a criterion of recent sewage pollution?

Yes.

3. To pronounce a water sewage polluted, would you require as evidence that B. coli was present in a majority of one cubic centimeter samples?

Yes, in general."

These opinions or the opinions expressed by these writers coincide with my own experience based on a considerable number of examinations for the presence of bacillus coli communis. It is my judgment that the relative abundance rather than simple presence of this organism should be considered in sanitary water analysis.

I may add furthemore, that my own opinion as to the significance of the abundance of bacillus coli communis in the waters of a flowing stream, has been greatly strengthened by some recently published investigations in a report on water purification investigation, and on plans proposed for sewerage and waterworks systems published by the sewerage and water board of New Orleans, Louisiana, 1903.

9626 The work included in this report has been largely carried out under the supervision of Mr. G. W. Fuller, of New York, who I understand has already testified as a witness in this case.

I quote from page 47 of this report, paragraph headed "Bacillus coli Communis:"

"In waters which contain unpurified sewage, the test for this intestinal organism is of the utmost importance. In the Mississippi river at New Orleans, however, there is evidently so much self-purification effected by natural agencies, such as dilution, sedimentation, etc., that this normal intestinal bacillus was one of the least common of the forms isolated. In about 100 tests with volume of water varying from one to 300 cubic centimeters, its presence was demonstrated only three times, although the larger samples of water were concentrated in a centrifuge before being seeded into the media contained in fermentation tubes."

The remarkable fact that bacillus coli communis was discovered only rarely in the water of the Mississippi river at

this point even when large amounts of water were tested, illustrates the condition that is likely to prevail in a river water of this character when protected from the entrance of
9627 polluting matters during a considerable part of its course.

I quote further from page 49 of this New Orleans report:

"From what goes before, it will be seen that the Mississippi river at New Orleans as evidenced by the data obtained during this investigation is unusually pure from a sanitary standpoint. For instance, it is believed that if 100 cubic centimeter samples of water were taken from the Merrimac, at Lawrence; the Hudson below the Mowhawk, the Schuylkill, the Potomac, the Ohio at Cincinnati, they would show the presence of bacillus coli communis as a rule. Such is not the case with the Mississippi river water at New Orleans, because as stated above, the opportunities for natural purification are so great during the last few hundred miles of its flow, and the amount of additional pollution received, is so small in comparison to the discharge of the river, that the bacteria which one is accustomed to consider to be the normal inhabitants of surface water effectually crowd out those abnormal bacteria which are carried into the river with the drainage from populated and cultivated areas. It must also be remembered that the banks of the Mississippi above New Orleans are protected by levees. These levees also in turn protect the river from contamination, except where sewers exist..
9628 Since it is usually more convenient for the towns immediately above New Orleans to carry their drainage away from the river almost no local pollution exists."

It is in my opinion certainly a striking and highly remarkable circumstance that the Mississippi river at New Orleans after receiving countless millions of colon bacilli contributed by the cities of the Ohio, Illinois, Mississippi and Missouri valleys, together with those on the many tributary streams and bearing in mind the facts already instanced as to the relatively high longevity of the colon bacillus, should show itself so nearly free from organisms of this class.

This condition furnishes a singular confirmation of the views that have been expressed regarding the sanitary significance of this organism when found in water supplies.

MR. JEFFRIES: I move to strike out all that the witness has read into the evidence from various publications, for the reason that the same is incompetent, and for the further reason that the evidence of the persons writing the articles is the best evidence and their production upon the witness stand should be had in order to give complainants an opportunity to 9629 cross-examine them with reference to the statements made or purported to have been made by them as detailed in evidence by this witness.

Q. MR. TODD: Will you state the methods employed by you in the determination made for the bacillus coli communis?

A. Two methods were employed in these determinations, one consisting in the mixing of a measured quantity of the water sample with broth containing a small amount of carbolic acid. Incubation of this broth was then resorted to and the resulting growth plated out on litmus lactose agar. The red colonies that developed resulting from the fermentation of the lactose, were picked from the plate and studied in regard to further characteristics. This method may be briefly designated as the carbol-broth method.

A second method which may be denominated the fermentation tube method, was also employed in a considerable portion of the work. This method consisted in inoculating a measured quantity of the water into Dextrose broth fermentation tubes (photographs of these fermentation tubes will be subsequently shown).

The use of the fermentation tube depends upon one of the most characteristic properties of the colon bacillus, namely its ability to produce gas by the fermentation of grape sugar. 9630 In some cases plates were made from the tubes showing gas production, and the colonies that developed were studied in detail, and complete identification arrived at. Throughout a large part of the work, however, the adoption of a more speedy method was rendered necessary by the large number of water samples to be examined, and what is known as the presumptive test for the presence of the bacillus coli was applied. The interpretation that I have adopted for this presumptive test is as follows:

Positive reactions—that is those indicating the presence of B. coli were regarded as those tubes showing gas production amounting to over 20 per cent of the tube length, the tubes yielding on absorption hydroxide with sodium, a gaseous residue appreciably in excess of the carbon dioxide absorbed. Negative reactions were those showing:

(a) No gas production, or

(b) gas production less than ten per cent of the tube length.

The doubtful class was made to include:

(a) those tubes yielding only ten to twenty per cent of gas. and

(b) those yielding more than twenty per cent with an ap-
9631 preciable excess of carbon dioxide. Any method susceptible of rapid application, like the one just outlined, leads to occasional misinterpretation, but the following data indicate that where a large number of water samples are treated, the error is not unduly large. The organisms were isolated from a series of 63 fermentation tubes and studied in detail, and complete identification was arrived at. The results summarized, were as follows:

In 39 cases the interpretation was positive, and a typical bacillus coli communis, responding to the most rigorous bacteriological tests, was isolated.

In 7 cases where the interpretation was positive, bacillus coli was not isolated. At least part of these and in my opinion probably all of these negative results were due to the fact that the colon bacillus originally present in the tube was overgrown by other forms and so missed at the plating; that this often occurs when the fermentation tube stands too long is well known to sanitary water analysts.

In 9 cases where the interpretation was doubtful, the bacillus coli was not isolated.

In 4 cases, where the interpretation was doubtful the typical bacillus was isolated.

9632 In 4 cases, where the interpretations were negative, bacillus coli was not isolated, and in addition, some twenty tubes were examined which showed growth in the closed arm, but yielded no gas producing organisms of any kind.

Such a presumptive test must always be open to the possibility of occasional misinterpretation, but in view of the data just cited, I cannot believe that the margin of error from this source is so great as to vitiate in any degree the results obtained.

In support of my opinion as to the value and importance of the presumptive test for the presence of the bacillus coli in water, I may cite some conclusions in a paper by Mr. George C. Whipple, of Brooklyn, who I understand has already testified as a witness in this case. The paper is entitled "On the Practical Value of presumptive tests for Bacillus Coli in Water." It was printed in the "Technology Quarterly, published at the Massachusetts Institute of Technology", volume 16, No. 1, March, 1903. I quote from page 31:

"The methods necessary for the certain identification of bacillus coli in water involved technique so complicated and so time consuming that they are not practical as working tests in connection with the supervision of water supplies.

9633 2. The fermentation of Dextrose broth as first suggested by Dr. Theobald Smith, furnishes the most rapid and most practical test for the presence of bacillus coli in water.

3. The extension of this test to cover different quantities of water in the same samples, thus making the test quantitative, within limits as well as qualitative, greatly enhances its value.

5. But whether or not bacillus coli is simply an intestinal germ, the fermentative test described above is a useful test to determine the sanitary quality of water and is one which gives results that agree well with chemical and biological analyses."

At another point in this same paper, page 22, Mr. Whipple says:

"Speaking broadly the typical reactions offer satisfactory presumptive evidence of the presence of this species (B. coli-communis) or species very closely allied to it. In a subsequent paper I hope to give the data to support this assertion, but at this time will offer as corroborative testimony, the statement of Mr. Irons, who in his paper on some observations of 9634 methods for the detection of the bacillus coli communis in water, states:

"When the Dextrose tube yields approximately 33 per cent of carbon dioxide, bacillus coli communis is almost invariably present."

The work of Mr. Irons here referred to was done in my laboratory in connection with the analyses that are now being considered.

9635 From all my experience upon the value of presumptive tests for B. coli, I am obliged to believe that this test is of high value in sanitary water analysis, and enables conclusions to be drawn as to the presence or absence of the colon bacillus which are in the main thoroughly satisfactory and decisive.

Q. The table of colon determinations which you have prepared regarding the preparation of which you testified to, cover what period of time?

A. They cover determinations made upon samples of water collected between May, 1899 and the end of June, 1900.

Q. From what places were the samples of water collected and by whom, for the colon determination, as evidenced by the tables which you have prepared?

A. These determinations were made from the bacteriological samples collected by the same water takers and at the same times as heretofore specified in my testimony. The colon determinations cover the samples obtained from the following stations:

Illinois and Michigan canal, Lockport,
Drainage canal, Kedzie Avenue,
Drainage canal, Locgkport,
9636 Desplaines river, Lockport,
Kankakee river, Wilmington,
Illinois river, Morris,
Fox River, Ottawa,
Illinois river, Ottawa,
Big Vermillion river, LaSalle,
Illinois river, LaSalle,
Illinois river, Henry,
Illinois river, Averyville,
Illinois river, Wesley City,
Illinois river, Havana,
Sangamon river, Chandlerville,
Illinois river, Grafton,
Mississippi river, Grafton,
Mississippi river, Alton, cross-section,
Missouri river, West Alton,
Mississippi river, Intake tower, St. Louis waterworks, Mitchell.
St. Lous tap water.

The chemical and bacterial determinations corresponding with these colon determinations, may be found by reference to the serial number and date.

9637 Q. Will you produce and read table No. 1?

A. Yes. It is as follows:

9638 Q. Will you explain the results shown in this table, and their sanitary significance?

A. Table No. 1 contains the results of colon determinations made upon samples of water from the Illinois and Michigan canal at Lockport, between August 29th, 1899 and June 26th, 1900. Owing to the large numbers of colon bacilli present in the water of this canal, it was found necessary to examine small quantities of water.

The numbers at the head of the five columns indicate quantities of water used in the several tests, namely, .00001 of a cubic centimeter; .0001 of a cubic centimeter; .001 .01 of a cubic centimeter and .1 of a cubic centimeter.

The sewage was diluted in each case by mixing with exactly measured quantities of sterilized water, one cubic centimeter of the dilution being added to the fermentation tube.

The signs "plus" "minus" and "interrogation point" in each column have reference to the positive, negative or doubtful outcome of the test. The criteria upon which these tests have been based have been already explained in detail. The table shows that in this highly polluted water the bacillus coli was *occasionally* present in so small an amount of water as
.0001 of a cubic centimeter, and that it was *usually* pres-
9639 ent in so small an amount of water as .0001 of a cubic
centimeter.

Q. Will you produce and read table I. B.?

A. Yes sir. It is as follows:

TABLE I-B.

(Drainage Canal, Kedzie Avenue.)

Serial	Date.	.00001			.0001			.001			.01 c. c.			.1 c. c.		
Number.	1900.	+	—	?	+	—	?	+	—	?	+	—	?	+	—	?
1789	May 8.	0	1	..	0	1	..	2	0	..	1	0	..	..	..	..

1955	June 11.	..	..	..	0	0	1	2	0	..	1	0	..	1	0	..
1992	June 18.	..	..	..	1	0	..	1	0	..	1	0	..	1	0	..
2027	June 25.	0	1	..	0	2	..	0	1	..	0	0	1	..	..	..

Q. Will you explain the results shown in this table and 9640 their sanitary significance?

A. Table I B contains the results of colon determinations made upon samples of water taken from the drainage canal at Kedzie Avenue between May 8th and June 5th, 1900.

The greater dilution of the sewage in the drainage canal during this period as compared with the condition of the Illinois and Michigan Canal shown in table 1, is manifested by the comparatively rare occurrence of the colon bacillus in .0001 of a cubic centimeter of water, and its occasional absence, even when .001 of a cubic centimeter of the water was examined.

Q. Will you produce and read table I C?

A. Yes sir, it is as follows:

9641

2002	June 19.	..	..	..	0	1	..	0	0	1	1	0	..	1	0	..
2034	June 26.	..	..	..	0	1	..	0	0	1	1	0	..	1	0	..

Q. Will you explain the results shown in this table and 9642 their sanitary significance?

A. Table I C contains the results obtained from the examination of samples taken from the drainage canal at Lockport between April 17th and June 26th, 1900. The dilution shown in the drainage canal at Kedzie Avenue is shown also in the drainage canal at Lockport, the colon bacillus being present in all the samples of .1 of a cubic centimeter that were examined, and in many of those of .01 of a cubic centimeter, but being almost invariably absent in those where .001 of a cubic centimeter was examined.

ADJOURNED until 10:00 A. M., Thursday, December 3rd, 1903.

9643 10:00 A. M., Thursday, December 3rd, 1903. Continuation pursuant to adjournment.

Present, the Commissioner and same counsel representing the respective parties.

PROF. EDWIN O. JORDAN,

resumed the stand for further direct-examination by Mr. Todd, and testified as follows:

Q. Will you produce and read table II of the colon determinations?

A. Yes, it is as follows:

9644

TABLE II.

(Desplaines River, Lockport.)

Serial Number.	Date, 1899.	.01 c. c.			.1 c. c.			1 c. c.

1012	Nov. 28	0	3	..	0	2	..	..	..	..

9645 Q. Will you explain the results shown in this table and their sanitary significance?

A. Table 2 contains the results of colon determinations made upon the water of the Desplaines river between August 1st, and November 28th, 1899.

Q. Professor, I desire to call your attention to the testimony of Dr. Ravold. On page 150 of his testimony given in this case, Dr. Ravold testified that the colon bacillus was found in 72 per cent of the samples taken from the Bear Trap Dam at

Lockport, in the month of March, 1900, and at page 320 of his testimony he testified that the bacillus coli communis was found in 71 per cent of the samples collected from the St. Louis settling basins during the period from May 1st to October 31st, 1900. Would you infer from those statements that colon bacillus was present in the water of these settling basins in St. Louis in anything like the same proportion that it was in the water of the drainage canal at Lockport?

MR. JEFFRIES: I object to the question because it is leading and suggestive.

A. I certainly should not.

Q. Give your reasons?

A. It is very important in making the test for the colon bacillus, especially when a polluted water is being dealt
9646 with to use dilutions of the water high enough to prevent
the overgrowth of the colon bacillus by other sewage forms. I have frequently in my own experience, found that by the use of so large a quantity of water as one cubic centimeter of water, apparently negative results are obtained, while by examination of a smaller quantity of the same water, positive results invariably appear. The explanation for this phenonenon, which may prove very misleading, is that when a large quantity of a sewage polluted water is introduced into fermentation tubes, other forms of bacteria such as some of the anaerobic bacteria, are present. These overgrow the colon forms, leading to an apparently negative result, and thus completely obscuring the true interpretation. I have frequently encountered this difficulty in dealing with highly polluted waters, in using quantities as large as one cubic centimeter. It is my opinion that if the colon determination be carried out properly, with due regard to the difficulties here mentioned, the colon bacillus would be found to be present in every cubic centimeter of the water in the drainage canal. Indeed, my examinations have shown no fewer than several hundred colon bacteria per cubic
centimeter in the water of the drainage canal, and gener-
9647 ally, several thousands, while in the water of the Missis-
sippi river which is pumped into the settling basins at St. Louis, and in the tap water drawn from the tap in St. Louis, the number of colon bacteria never approximate anything like these figures.

For these reasons I am compelled to assume that the statements to which you refer are based on defective analytical methods, and do not indicate that the actual number of colon bacilli in the water of the drainage canal and in the St. Louis settling basins are at all comparable.

Q. Will you produce and read in evidence table III?

A. Yes, it is as follows:

9648

TABLE III.

(Kankakee River, Wilmington.)

Serial Number.	Date. 1899.	.1 c. c.			1 c. c.		
		+	—	?	+	—	?

981	Nov. 20	...	..	..	1	0	..

9649 Q. Will you explain the results shown in this table and their sanitary significance?

A. Table III contains the results of colon determinations made upon samples of water collected from the Kankakee river at Wilmington, between August 7th, and November 20th, 1899. They show that during this period the colon bacillus was frequently present in .1 of a cubic centimeter, and usually present in one cubic centimeter.

Q. Will you produce and read in evidence, table IV?

A. Yes, it is as follows:

TABLE IV.

9651 Q. Will you explain the results shown in this table and their sanitary significance?

A. Table IV contains the results of colon determinations made upon samples of water taken from the Illinois river at Morris between October 31st, 1899 and June 27th, 1900. They show that during the early part of this period the colon bacillus was generally present in .001 of a cubic centimeter of the water, while in the latter part of this period, namely from January 30th, 1900 to April 23rd, 1900, it was rarely present in this dilution. In fact, in May and June, 1900, the colon bacillus was even absent in quantities of .01 of a cubic centimeter, and occasionally absent in .1 of a cubic centimeter sample.

Q. Professor, will you explain what the double dots mean as they appear in the tables both preceding the one under consideration, as well as the one under consideration, and the subsequent tables in this series?

A. These dots signify that there were no determinations following under the several heads at these points. Thus, on May 29th, 1900, no examinations were made of the water from the Illinois river at Morris, in dilutions of .0001 and .001; that one examination of .01 was made, resulting negatively. Two examinations of .1 of a cubic centimeter were made, one 9652 of which was positive, one negative. Two examinations of one cubic centimeter of the water were made, both of which were positive. This system of record is used throughout this series of tables.

Q. Will you produce and read in evidence table V?

A. Yes, it is as follows:

9653

2035	June 26	0	1	..	1	1	..	1	0	..

9654 Q. Will you explain the results shown in this table and their sanitary significance?

A. Table V contains the results of colon determinations made upon samples of water taken from the Fox River at Ottawa between August 1st, 1899 and June 26th, 1900. They show that in this water the colon bacillus was rarely present in .1 of a cubic centimeter; was often present in one cubic centimeter and usually present in five cubic centimeters of water.

Q. Professor, will you produce and read in evidence table VI?

A. Yes sir. Table VI is as follows:

TABLE VI.

2036	June 26	0	1	..	0	1	..	1	1	..	1	0	..

9656 Q. Will you please explain what is shown by table VI and its sanitary significance?

A. Table VI contains the results of colon determinations made upon samples of water taken from the Illinois river at Ottawa, between August 1st, 1899 and June 26th, 1900. They show that during the greater part of this period colon bacillus was occasionally present in .01 of a cubic centimeter and that it was frequently present in .1 of a cubic centimeter.

Q. Will you produce and read in evidence table VII?

A. Yes sir. It is as follows:

9657

TABLE VII.

(Big Vermillion, La Salle.)

Serial Number.	Date, 1899.	.1 c. c.			1 c. c.		
		+	—	?	+	—	?
388	Aug. 2	0	5	..	0	1	..
423	Aug. 9	..	..	..	0	0	1
502	Aug. 23	0	1	..	0	0	1
533	Aug. 30	0	1	..	0	1	..
882	Nov. 1	1	0	..	1	0	..
920	Nov. 8	..	..	..	0	1	..
959	Nov. 15	..	..	..	0	1	..
988	Nov. 22	0	1	..	1	0	..
1017	Nov. 28	0	1	..	1	0	..

9658 Q. Please explain what is shown by table VII, and its sanitary significance?

A. Table VII contains the results of colon determinations made upon samples of water taken from the Big Vermillion river at LaSalle, between August 2nd, and November 28th, 1899. The colon bacillus was commonly absent in .1 of a cubic centimeter of water, and found only about half of the time in one cubic centimeter samples.

Q. Will you produce and read in evidence table VIII?

A. Yes sir. It is as follows:

9659

TABLE VIII.

(Illinois River, La Salle.)

Serial Number.	Date, 1899.	.1 c. c.			1 c. c.		
		+	—	?	+	—	?
389	Aug. 2	..	..	..	0	0	1
424	Aug. 9	1	0	..	0	0	1
503	Aug. 23	0	1	..	0	0	1
534	Aug. 30	0	1	..	0	0	1
883	Nov. 1	1	0	..	1	0	..
960	Nov. 15	0	1	..	1	0	..
989	Nov. 22	0	1	..	0	0	1
1018	Nov. 28	0	1	..	1	0	..

9660 A. Please explain what table VIII shows and its sanitary significance?

A. Table VIII contains the results of colon determinations made upon samples of water taken from the Illinois river at LaSalle between August 2nd, and November 28th, 1899. The number of colon bacteria found here corresponds very closely with the number found in the Big Vermillion river, it being noted that the samples were taken at these two points on the same dates.

Q. Will you produce and read in evidence table IX?

A. Yes sir, it is as follows:

9661

TABLE IX.

(Illinois River, Henry.)

Serial Number.	Date, 1899.	.01 c. c.			.1 c. c.			1 c. c.

2006	June 20	..	..	..	0	1	..	2	0	..
2041	June 27	..	..	..	0	1	..	0	2	..

9664 Q. Please explain what table X shows and its sanitary significance?

A. Table X contains the results of colon determinations made upon samples of water taken from the Illinois river at Averyville, between June 9th, 1899 and June 27th, 1900.

The relatively large number of colon bacteria present in the Illinois river at Morris as shown in table IV has been greatly diminished between Morris and Averyville, so that while at Morris the colon bacillus was found almost invariably in .1 of a cubic centimeter of water, at Averyville it was but rarely present in this amount of water, and occasionally absent even in one cubic centimeter of water.

This group of organisms appear to have suffered a great mortality in the water between Morris and Averyville.

Q. Will you produce and read into evidence table XI?

A. Yes sir, it is as follows:

9665

TABLE XI.

(Illinois River, Wesley City.)

Serial Number.	Date, 1899.	.0001 c. c.			.01 c. c.			.1 c. c.			1 c. c.

9666 Q. Please explain what table XI shows and its sanitary significance?

A. Table XI contains results of colon determinations made upon samples of water taken from the Illinois river at Wesley City, between June 9th, 1899 and June 28th, 1900.

The increased pollution of the river at this point is shown by the swollen number of colon bacilli, which were found quite often in .1 of a cubic centimeter of water.

Q. Will you produce and read in evidence table XII?

A. Yes sir, it is as follows:

9667

TABLE XII.

(Illinois River, Havana.)

Serial Number.	Date, 1899.	.1 c. c.			1 c. c.

699	Sept. 29	0	1	..	0	1	..

9668 Q. Please explain what table XII shows and its sanitary significance?

A. Table XII contains the results of colon determinations made upon samples of water taken from the Illinois river at Havana between June 7th and September 29th, 1899. The colon bacillus was commonly present in one cubic centimeter of water.

Q. Will you produce and read in evidence table XIII?

A. Yes sir, it is as follows:

9669

TABLE XIII.

(Sangamon River, Chandlerville.)

2051	June 28	0	2	..	0	1	1	1	0	..

9670 Q. Please explain what table XIII shows and its sanitary significance?

A. Table XIII contains the results of colon determinations made upon samples of water taken from the Sangamon river at Chandlerville, between June 8th, 1899, and June 28th, 1900. As has before been stated, the Sangamon river receives above Chandlerville the sewage of a very considerable urban population, and this condition is reflected in the relatively high number of colon bacilli, which during the period covered by these determinations, range much higher than the number found in the water of the Illinois river at Averyville, as evidenced especially by the determinations made of .1 of a cubic centimeter samples. The colon bacillus was even found occasionally in .01 of a cubic centimeter of water taken from the Sangamon river at this point.

Q. Will you produce and read in evidence table XIV?

A. Yes sir, it is as follows:

9671

9672 Q. Please state what table XIV shows and its sanitary significance?

A. Table XIV contains the results of colon determinations made upon samples of water taken from the Illinois river at Grafton between June 8th, 1899, and June 29th, 1900.

The colon bacillus was present in .1 of a cubic centimeter samples in about the same proportion as at Averyville, and was present in the majority of one cubic centimeter samples, as is usually found to be the case with unprotected surface waters receiving at more or less frequent intervals the drainage of urban and rural communities.

Q. Will you produce and read table XV?

A. Yes sir, it is as follows:

9673

9674 Q. What does table XV show and what is its sanitary significance?

A. Table XV contains the results of colon determinations made upon samples of water taken from the Mississippi river at Grafton between June 8th, 1899, and June 29th, 1900. The colon bacillus was found during this period not infrequently in .1 of a cubic centimeter samples, and in the majority of one cubic centimeter samples, being in this respect like the Illinois river, a typical unprotected surface water.

Q. Will you please produce table XVI and read it in evidence?

A. Yes sir, it is as follows:

9675

9678 Q. Please explain what table XVII shows and its sanitary significance?

A. Table XVII contains the results of colon determinations made upon samples of water collected in the Missouri river at West Alton, Missouri, between July 28th, 1899, and June 28th, 1900. During this period the colon bacillus was found quite commonly in .1 of a cubic centimeter of water, especially in the months of May and June, 1900, and was commonly present in the one cubic centimeter of water samples.

Q. Will you produce and read table XVIII?

A. Yes sir, it is as follows:

9679

TABLE XVIII.

(Mississippi River, Intake Tower, St. Louis Waterworks, Mitchell.)

9680 Q. Please explain what table XVIII shows and its sanitary significance?

A. Table XVIII contains the results of colon determinations made upon samples of Mississippi river water collected at the intake tower of the St. Louis waterworks, between July 14th, 1899 and June 29th, 1900.

The results show a general similarity with those obtained from the water of the Missouri river at West Alton.

Q. Will you produce and read in evidence table XIX?

A. Yes sir, it is as follows:

9681

9682 Q. Please explain what is shown by table XIX and its sanitary significance?

A. Table XIX contains the results of colon determinations made upon samples of St. Louis tap water taken between July 7th, 1899, and June 29th, 1900.

The smaller number of colon bacteria in .1 of a cubic centimeter samples, as compared with the number found in the Mississippi river at the water intake indicates a considerable diminution in the number of colon bacteria during the passage through the settling basins and water pipes.

Q. Professor, have you a table of summaries of results for the principal stations on the Illinois river?

A. I have. It is as follows:

9683

I. PRINCIPAL STATIONS ON THE ILLINOIS RIVER.

Collecting Stations.	.00001 c. c.		.0001 c. c.		.001 c. c.		.01 c. c.		.1 c. c.

9684 Q. Will you please explain what the table shows?

A. This table summarizes the results obtained from the colon determinations made upon the waters collected at the principal stations along the Illinois river. It shows that in the water of the Illinois and Michigan canal at Lockport the bacillus coli was present in .001 of a cubic centimeter of water on 28 days out of 32 days on which examinations were made. It shows further that in the water of the Illinois river at Morris the colon bacillus was present in .01 of a cubic centimeter of water on 20 days out of 30 days on which examinations were made, while at Ottawa it was present in the same quantity of water on only 6 days out of 22 days on which examinations were made.

At Ottawa the colon bacillus was found in .1 of a cubic centimeter of water on 19 days out of 34 days on which examinations were made, while at Averyville it was found in the same quantity of water on only 5 days out of 27 days on which examinations were made.

The increased pollution of the water at Wesley City is shown by a larger number of colon bacilli as indicated by the fact that the colon bacillus was found in .1 cc of water from this point on 13 days out of 26 days, on which examinations were made, or more than three times as frequently as in the Illinois river at Averyville above Peoria.

9685 At Grafton at the mouth of the river the colon bacillus was found in .1 of a cubic centimeter on 13 days out of 35 days on which examinations were made.

These summaries show that the colon determinations coincide with the results of the routine chemical and bacterial examinations already referred to.

The processes of oxidation of the organic matter, the death of the mass of sewage bacteria and the mortality among the specially significant group of colon organisms appear to run a closely parallel course, and the inference as to the purification of the stream drawn from the chemical analyses and from the count of bacterial colonies, is further emphasized by the mortality shown to occur in this significant class of sewage bacilli.

Q. Have you a table of summaries comparing the Illinois river at Averyville and Grafton with the tributaries of the Illinois, and with the Mississippi river above Grafton and the Missouri river at West Alton?

A. I have. It is as follows:

9686

9687 Q. Please explain what this table shows and its sanitary significance is?

A. This table contains a summary of the results of the colon determinations made upon the Illinois river at Averyville and Grafton, compared with the tributaries of the Illinois and with the Mississippi and Missouri rivers.

On comparing the number of days on which bacillus coli was found in one cubic centimeter, samples of water taken from the Illinois river at Averyville, with those taken from the Illinois river at Grafton, from the Mississippi river at Grafton, from the Desplaines river, from the Kankakee river; from the Fox river, from the Big Vermilion river; from the Sangamon river, and from the Missouri river, it appears that so far as the colon content enables one to pass an opinion as to the sanitary quality of these waters the Sangamon river at Chandlerville, is one of the more highly polluted streams.

The Illinois river at Grafton, the Mississippi river at Grafton and the Missouri river at West Alton appeared to be on substantially the same footing with one another in respect to their colon conent, while the Fox river contained a smaller proportion of colon bacilli than any of the streams under consideration.

9688 The Illinois river at Averyville compares in respect to its colon content very favorably with the Illinois, Mississippi and Missouri rivers and is perceptibly less highly contaminated than the water of the Sangamon river at Chandlerville.

Summing up these facts in the second division of this table it is seen that samples of water taken on 69 different days from the Illinois river at Averyville and at Grafton contained bacillus coli communis on 39 days, while the various tributaries of the Illinois river, samples from which were taken on 69 days, contained colon bacillus on 36 days. Samples taken from the waters of the Missouri on 66 days contained colon bacillus on 44 days.

It appears therefore from these tables, that if the opinion that I have expressed regarding the sanitary significance of the colon bacillus in water is correct, the water of the Illinois river at Averyville and Grafton was not materially different from what it would have been if the tributaries of the Illinois, exclusive of the Desplaines river and its sewage content, had alone fed the basins of this stream. The colon content of such a stream at Averyville and at Grafton would have been sub-
9689 stantially what it is at present.

Q. What sanitary significance do you attach to the tables of colon determinations as presented in evidence by you, considering them as a whole?

A. As stated in my testimony of yesterday, my experience leads me to adopt the view that the relative abundance of the colon bacillus in water affords the most satisfactory single analytical indication that sanitary science at present possesses as to the sanitary quality of a natural water.

Basing my opinion upon this I may say that I regard the relative abundance of colon bacilli in the water of the Illinois river at various points, and in the various tributary streams as furnishing a highly important clew to the freshness of the pollution entering, and the amount of real purification undergone by each stream. Considered from this standpoint the water of the

Illinois river at Averyville and at Grafton, is no more impure than the water in the principal tributaries of the Illinois, and certainly no more impure or dangerous than the water of the Mississippi river at Grafton, or the Missouri river at West Alton. The successive and striking diminution in the number of colon bacilli at various points along the Illinois river from Lockport to Averyville, is proof in my judgement of the occurrence of a process of genuine self-purification.

9690 Q. What sanitary significance, do you attach to your chemical, bacteriological and colon determinations heretofore introduced into evidence, as evidenced, by the tables introduced for the period extending from May, 1899 to the end of June, 1900?

A. I regard these determinations as forming a connected and correlated whole, mutually sustaining one another, and all pointing in my judgment, to but one interpretation. The oxidation of the organic matter that was introduced in enormous quantities at Lockport, the more or less complete destruction of the sewage bacteria also introduced at this point, and especially the high mortality among the colon bacteria occuring in the upper stretches of the river, all appear to me to indicate that infectious matters that might have been introduced into the sewage of Chicago and found their way into the drainage canal during this period from May 1899 to the end of June 1900, did not make their way down river so far as Averyville. So far as my interpretation of the results of the chemical analyses, the bacterial counts and the colon determinations is concerned, I have no hesitation in expressing as my opinion that the water of the Illinois river at its mouth is no more liable to convey disease or to produce injurious consequences of any kind than the waters of the Mississippi river at this point, or the water of the Missouri river at West Alton. In expressing this
9691 opinion I am taking into consideration all the knowledge that I have acquired by personal experience and all the information that I have obtained regarding the chemical and bacterial content of these waters during the period under consideration.

MR. JEFFRIES: I move to strike out all the inferences, conclusions and opinions of this witness based upon the tables of analyses with reference to the period from May 1899 to the close of the year 1900, for the same reasons given and stated in my objection to the introduction of the tables themselves.

ADJOURNED until 2:00 P. M. same day.

9692 2:00 P. M., Thursday, December 3rd, 1903. Continuation pursuant to adjournment.

Present, the Commissioner and same counsel representing the respective parties.

PROF. EDWIN O. JORDAN,

resumed the stand for further direct-examination by Mr. Todd, and testified as follows:

Q. Professor, did you make any survey of the waters of the Illinois river, the Mississippi and the Missouri rivers, in 1901?

A. I did.

Q. State the circumstances which led up to the making of this survey?

A. So far as I understand these circumstances, an agreement was reached between the authorities of the State of Missouri and the State of Illinois for conducting a joint investigation of the water of the rivers named, at certain points. The aim of this joint examination was as I understand it, to secure that the samples should be taken at specified places, at specified times, and under uniform conditions.

9693 Q. What part did you have in connection with this investigation?

A. I was asked by Dr. Arthur R. Reynolds, director of the Streams Examination to establish and equip three laboratories; one at Peoria on the Illinois river; one at Grafton at the mouth of the Illinois river, and one at St. Louis. At these laboratories samples of water were to be examined bacterially by methods left to my discretion. These laboratories were accordingly established in October, 1901, under my direction, and work continued up to the end of December, 1901.

The laboratory at Peoria was under direct charge of Mr. F. W. Schule; that at Grafton under the charge of Mr. W. S.

Sayer; and that at St. Louis in charge of Mr. E. E. Irons, and Mr. W. G. Sackett. I believe that all these gentlemen except Mr. Irons, have already testified in this case.

Q. They were all under your direction and supervision?

A. Yes. Mr. Irons in addition to carrying out much of the work in the St. Louis laboratory personally had supervision of all three laboratories, visiting them at intervals and reporting to me. In addition, the workers in charge of the three laboratories sent in weekly written reports to me at the University of Chicago, keeping in addition, duplicate copies of these reports in their laboratories, all of which were finally turned over to me for final scrutiny. 9694

The work carried out at these three laboratories consisted chiefly in plating samples of water daily and also in making daily colon determinations. Data were secured regarding the temperature of water and air at the time of collection, the hour of plating, etc. Besides this routine work in the laboratory, the different workers were instructed by me to select from the colonies of bacteria appearing upon the plates, all the different kinds of bacteria that could be distinguished by their growth upon the medium used. These different colonies thus picked off the plates were transferred to agar tubes which were shipped by express to me at the bacteriological laboratory at the University of Chicago, where they were studied in detail. All of the work in all three laboratories was under my supervision. My assistants were given careful and minute instructions regarding all details of laboratory procedure, and so far as I could determine from inspection of the work and its results, these instructions were scrupulously followed.

9695 Q. At what points were samples of water collected for examination in these three different laboratories?

A. The work carried on at the Peoria laboratory comprised examinations of samples of water taken from the Illinois river at two different localities; namely, at Averyville, above Peoria and at Pekin, below Peoria; the precise points of collection were approximately those selected for the investigation of 1899 and 1900.

The laboratory at Grafton dealt with samples of water collected from the Illinois river at its mouth (above the point where any mixing with the Mississippi river water was possible), and from the Mississippi river above Grafton, the precise points of collection being the same as in the 1899 and 1900 series.

In the laboratory at St. Louis examinations of five samples of water were regularly made, namely, from the Mississippi river at the chain of rocks, a cross section of four samples being taken at this point, the points of collection being those specified in the 1899 and 1900 series. The fifth sample was obtained from the Missouri river at Fort Bellefontaine, West Alton.

Q. What instructions were given by you for the planting of these samples relative to the time of collection?

9696 A. The various laboratory workers were directed to plate the samples of water as soon after collection as possible, in every case.

Q. What determinations were made in these different laboratories?

A. The work done during this period was wholly bacteriological in character and may be grouped conveniently under three heads:

(a) The determination of the number of bacteria in the river water as shown by the ordinary colony counts.

(b) The number of germs of the colon group in the river water as shown by the Dextrose fermentation tube test.

(c) Study of the species of bacteria isolated from the river water.

The first two determinations were carried out in the respective branch laboratories, and it is certain that a decided gain in the accuracy of the results was attained by conducting this work at or near the points of collection, upon freshly collected samples, instead of allowing as in the previous work, a considerable interval to elapse while samples were being transported to a distant point. The detailed study of the bacterial species was carried out under more advantageous conditions of-
9697 fered for this kind of work by the University laboratories.

Q. What methods were employed in making all these determinations?

A. The methods used for the numerical estimation of the germs in the river water were those originally recommended by the committee upon Standard Water Analysis, appointed by the American Public Health Association (Science 1900, December 14, pages 906 to 915), together with the conditions and modifications embodied in the report of this committee presented at the Buffalo meeting of this association in 1901, (Reports and papers of the American Public Health Association, 27, page 377). Gelatin of a standard reaction (one per cent acid to phenolphthalein) was employed as the nutrient medium and in order to insure strict comparability between the results obtained in the several laboratories, all gelatin used in the three laboratories was made by Mr. Irons in the St. Louis laboratory. In my opinion it was because of this uniformity in method that the results in the several laboratories sustained a close and constant relation here to one another and can be legitimately compared. The counts of the bacterial colonies appearing on the gelatin plates have been made after 48 hours incubation, at an average temperature of 20 degrees centigrade. Several different decimal dilutions of the water were usually employed, the dilution that was selected for record in the accompanying tables was always, where possible, the one showing from about 25 to 125 colonies on a plate. The method used for estimating the number of colon bacteria in the river was the Dextrose fermentation tube method and was sufficiently described in connection with the 1899 and 1900 series. All the results detailed in the tables that I have prepared were obtained by this method, and the system adopted for recording the results was the same as in the preceding work. The methods used in the study and differentiation of species were those generally employed in the best bacteriological laboratories in this country. 9698

Q. Have you the tables prepared at the different stations where these determinations which you have just described were made?

A. I have.

Q. The data from which those tables were made were obtained in what manner, Professor?

A. From reports made to me by my assistants at the several laboratories.

Q. Were these analyses made at the different laboratories, made under your direction and supervision?

A. Entirely so.

9699 Q. The results of the analyses made by your subordinates located at the different laboratories were communicated to you in what manner?

A. In writing, each report being signed by the man sending it.

Q. Have you these reports with you from which the tables which you have prepared, were made?

A. I have them all here.

Q. Will you produce them?

(Witness produces tables.)

MR. TODD: I offer the original analytical report from the laboratory at St. Louis made by W. G. Sackett, that at Grafton made by W. S. Sayer, and that at Peoria made by F. W. Schule, to Professor E. O. Jordan of the Chicago University, under whose direction and supervision these analyses were made. Also the coli determinations made by the same parties at the three different laboratories for this period and reported to Professor Jordan in the same manner as above indicated. These reports are offered for the inspection of counsel and will be made a part of the evidence if objection is made to their non-introduction.

Q. Have you the tables made by you from the examinations at the Peoria laboratory?

A. I have.

9700 Q. How many tables have you made of the determinations made at Peoria?

A. Two sets, one covering the samples of water collected at Averyville, the other covering those collected at Pekin, below Peoria.

Q. Will you produce and read the table for the determinations made at Averyville in the Peoria laboratory?

A. I will. It is as follows:

22 8.00 9.00 4 -5 29.58 1-10 1) 1600

General average, 5800.

9705 Q. Will you state what the table that you have just read shows, and its sanitary significance?

A. This table contains the results of daily bacterial determinations made upon samples of water from the Illinois river at Averyville between October 9th and December 30th, 1901. On this table are specified the date of collection, the hour of collection and the hour of plating, the temperature in degrees centigrade of the water and air; the height of water; the dilution in which the sample was plated, the number of colonies per cubic centimeter (two samples in most cases) and the average of these daily determinations. Throughout October and

November the numbers of bacteria in the water as shown by the colony count were low; the counts showing often only a few hundred colonies per cubic centimeter. In December the numbers increased somewhat and in the latter part of December, the numbers are on several occasions in the tens of thousands.

So far as the bacterial count is concerned, these examinations show that the water of the Illinos river at this point was in a condition which considered as a river water, was fully up to the average of river waters in this country.

9706 Q. Will you produce and read the table showing the determinaitons made at the Peoria laboratory for the point at Pekin?

A. Yes, sir. It is as follows:

9707 ILLINOIS RIVER—Pekin (Below Peoria).

General average, 90000.

9710 Q. What does this table show and what is its sanitary significance?

A. This table shows the results of colony counts made from samples of water collected from the Illinois river at Pekin between October 16th and December 13th, 1901, the same data being given as in the table for Peoria.

Throughout this period this water is characterized by a much higher bacterial content than the water of the Illinois river at Averyville. On October 26th, for example, the average number of four determinations at Pekin was 341,000, per cubic centimeter, while at Averyville on the same date there were only 890 colonies per cubic centimeter.

Q. Will you produce and read the table for the determinations made of the Illinois river at Grafton?

A. Yes, sir. It is as follows:

9711 ILLINOIS RIVER—Grafton.

Date 1901 Oct.	Hour of collection.	Plating.	Temperature C. Water.	Air.	Height of Water.	Dilution.	No. of Colonies per cc.	Averages.

9714

General Average 6900

9715 Q. Will you state what the table you have just read shows, and its sanitary significance?

A. This table contains the results of bacterial counts made from samples of water taken from the Illinois river at Grafton, between October 1st and December 24th, 1901. The data specified as given in the Peoria tables are given also in this table.

The numbers of bacteria per cubic centimeter found in the water of the Illinois river at Grafton are very similar to those found in the water of the Illinois river at Averyville.

9716 Q. Will you produce and read in evidence the table for the determinations made of the Mississippi river above Grafton?

A. Yes sir, it is as follows:

9717

MISSISSIPPI RIVER—Grafton.

General average, 1300.

9721 Q. Will you state what the table you have just read shows, and its sanitary significance?

A. This table contains the tabulations of colony counts made from samples of water obtained from the Mississippi river at Grafton between October 1st, 1901, and December 24th, 1901, other data specified in the Peoria tables being also included in this table. Throughout most of the period covered the results correspond rather closely with those obtained upon the Illinois river at its mouth.

Q. Have you a series of tables for the cross-section of the Mississippi river at the chain of rocks?

A. Yes, sir.

Q. Will you produce and read those tables?

A. Yes, sir; the tables are as follows:

9722 MISSISSIPPI RIVER—Chain of Rocks—Illinois Shore.

Date 1901 Oct.	Hour of collection.	Plating.	Temperature C.		Height of Water.	Dilution.	No. of Colonies per cc.		
			Water.	Air.					Averages.

9734 Q. State what those tables show and their sanitary significance?

A. These tables contain tabulations of colony counts made from samples of water taken from the Mississippi river at the chain of rocks between October 7th, 1901 and December 14th, 1901, at four points across stream, namely, those specified in the records of the cross section at this point for 1899 and 1900. These tables show that throughout the period covered the number of bacteria contained in the water taken from the Mississippi river at the intake tower and from the Missouri shore contained a noticeably larger number of bacteria than the water on the Illinois shore.

Q. Will you produce and read the tables showing the colony determinations from the Missouri shore at Fort Bellefontaine?

A. Yes sir, the tables are as follows:

9735

MISSOURI RIVER--Bellefontaine.

General average, 21000.

9738 Q. State what the table shows and its sanitary significance?

A. This table contains tabulations of colony counts made from samples of water collected from the Missouri river at Fort Bellefontaine between October 9th and December 16th, 1901; other data being included as hereinbefore specified. It shows that throughout this period the number of bacteria in the water of the Missouri river at this point was noticeably higher than in the water of either the Illinois river at its mouth, or the Mississippi river above Grafton.

Q. Have you prepared a table of averages from the table just read?

A. I have.

Q. Will you produce and read the table of averages which you have prepared?

A. Yes, sir; the table of averages is as follows:

9739

Collecting Station.	Number determination.	Average number colonies per cc Oct.-Dec., 1901
Illinois River, Averyville (above Peoria)	69	5800
Illinois River, Pekin (below Peoria)	50	90000
Illinois River, Grafton,	73	6900
Mississippi River, Grafton,	73	1300
Mississippi River, Chain of Rocks, Illinois Shore,	54	2400
Mississippi River, Chain of Rocks, Mid-stream,	53	5200
Mississippi River, Chain of Rocks, Intake Tower,	52	21200
Mississippi River, Chain of Rocks, Missouri Shore,	53	17000
Missouri River, Fort Bellefontaine,	51	21000

9740 Q. State what this table of averages shows and what conclusions you draw from it from a sanitary standpoint?

A. This table contains the averages of the colony counts made from the water of the Illinois river at Averyville, at Pekin and at Grafton; from the Mississippi river at Grafton, and in cross-section at the chain of rocks, and from the Missouri river at Fort Bellefontaine. The number of bacteria found at Averyville and at Grafton was not dissimilar. These averages were higher than the average for this period in the Mississippi river. The usual winter increase which occurs in river waters took place this year in the Illinois river before making its appearance in the Mississippi. Up to the middle of December, 1901, the two waters were very similar as regards their bacterial content. Throughout the whole of the period studied, the average number of bacteria as shown by the colony count in the water of the Missouri river at West Alton was several times as great as the water in either the Illinois river at its mouth or the Mississippi river above Grafton. The number of bacteria in the Illinois river at Pekin as shown by these averages was greatly in excess of that found at any other of the collecting stations, as in 9741 my opinion naturally follows from the entrance of the sewage and refuse of Peoria, into the river above this point.

Q. Have you a table of averages for the cross-section of the Mississippi river at the chain of rocks?

A. I have.

Q. Will you produce and read the table in evidence?

A. Yes, sir; the table is as follows:

9742

9744 Q. Will you state what the table shows and its sanitary significance?

A. This table contains the results of the bacterial counts made upon samples of water taken from the Mississippi river at the chain of rocks. The averages are arranged in their proper relation, namely, the Illinois shore, mid-stream, intake tower and Missouri shore, the count for the Missouri river being contained in the right hand column. These figures show that during the period covered by this investigation the number of bacteria in the water of the Mississippi river at this point was much lower on the Illinois shore than on the Missouri shore. It shows, moreover, that the water of the intake tower during this period partook of the character bacterially of the water of the Missouri river and of the Mississippi river on the Missouri shore. In other words, during these three months of 1901, judging from the bacterial content of the Missouri river and of the Mississippi river at this point, little, if any, water from the Illinois river entered the intake tower of the St. Louis waterworks. It is evident also from the bacterial count, that if any water from the Illinois shore did pass into the water intake, it improved the condition of this water so far as reducing the number of bacteria per cubic centimeter was concerned.

9745 Q. Have you stated in evidence the stages of water in the Illinois, Mississippi and Missouri rivers during the time of this investigation?

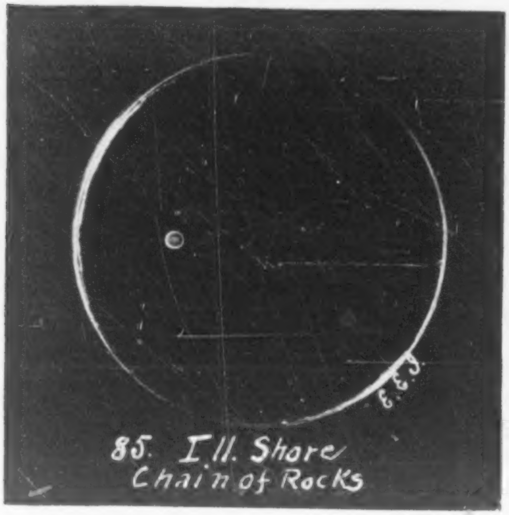
A. Yes, they are included in the detail tables which I have presented.

Q. Have you any photographs illustrating the different cross-sections of the Mississippi river at this point?

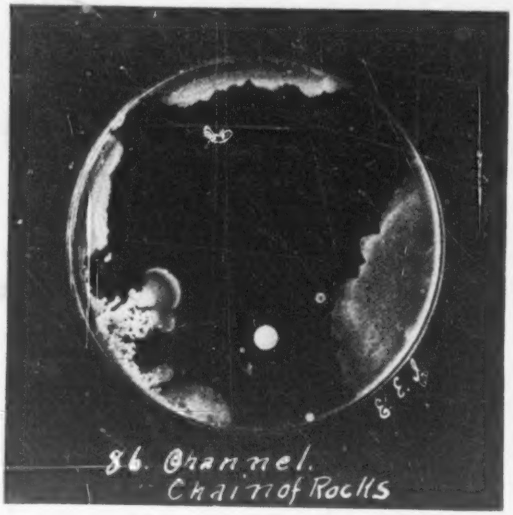
A. I have.

Q. Will you produce and identify the photograph which you hold in your hand so that the same may be incorporated into the record at this point?

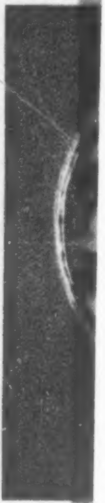
A. The photograph is as follows:



85. Ill. Shore
Chain of Rocks

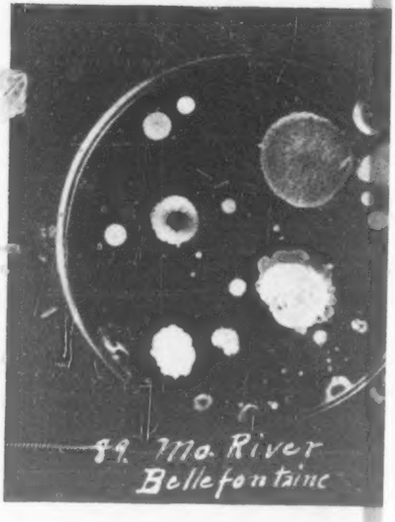


86. Channel.
Chain of Rocks



Bacteriological Laboratory.
University of Chicago.

PLATE I.



89. Mo. River
Bellefontaine

Photographs of Agar Plates
Showing
NUMBER OF COLONIES
in $\frac{1}{10}$ cubic centimeter
Developing in Different
Water Samples.

9747 Q. Will you please explain the photograph just introduced in evidence and made a part of the record and state what it shows?

A. To this card has been affixed five photopraphs of agar plates showing the number of colonies in .01 cubic centimeter, developing in different water samples collected from the Mississippi river in cross-section at the chain of rocks, and also from the Missouri river at Fort Bellefontaine on October 28th, 1901.

This is designated plate 1. These photographs show that the number of colonies appearing in the Mississippi river at the chain of rocks was at this date very much lower than the number in the Mississippi river at the intake tower and the Missouri shore, and also in the Missouri river.

These photographs are thoroughly representative of the results obtained at the chain of rocks throughout this period, October, November and December, 1901, and show clearly that the mingling of the water from the Illinois shore of the Mississippi river with the water of the Missouri river would tend to diminish the number of bacteria per cubic centimeter in the latter water.

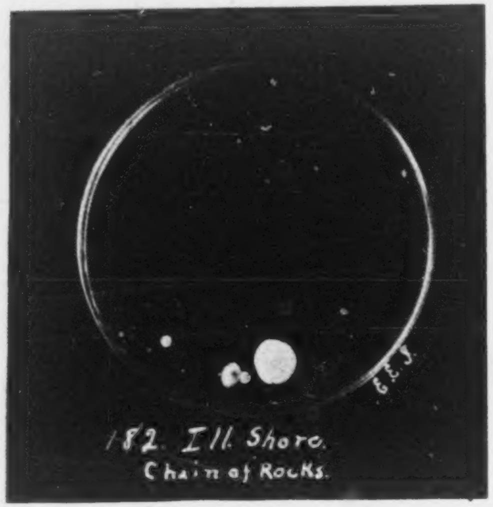
It is also evident from these photographs that the water 9748 entering the intake tower at the chain of rocks, was much more largely composed of Missouri river water than of Illinois river water.

Q. Have you prepared a plate of photographs of other samples taken at the cross-section of the Mississippi?

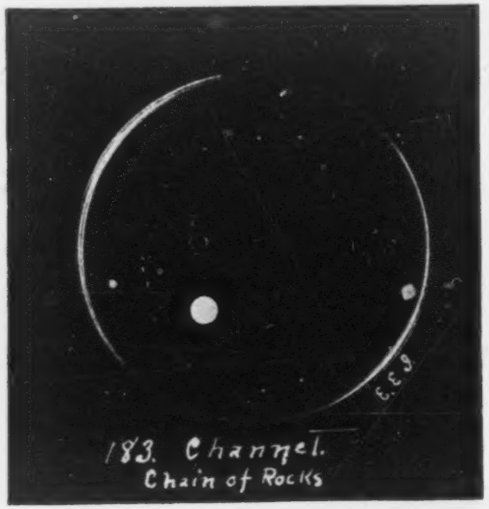
A. I have.

Q. Will you produce plate of photographs No. 2 so as to make it a part of the evidence on record in the case?

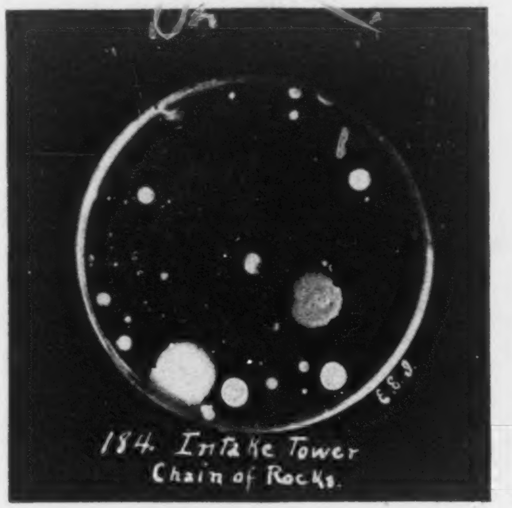
A. Yes, sir; plate 2 is as follows:



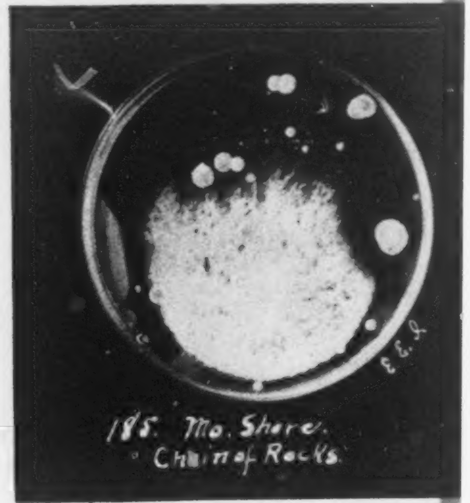
182. Ill. Shore.
Chain of Rocks.



183. Channel.
Chain of Rocks



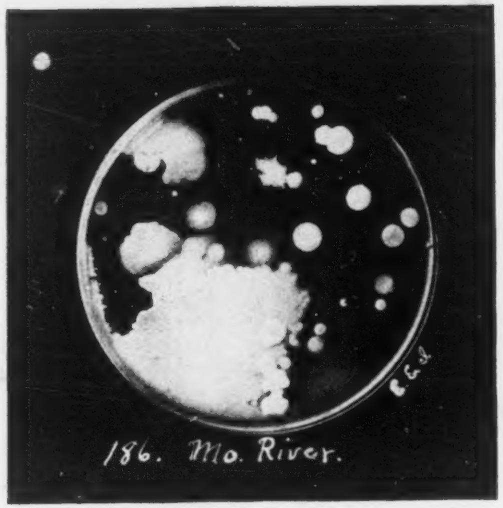
184. Intake Tower
Chain of Rocks.



185. Mo. Shore.
Chain of Rocks.

Bacteriological Laboratory.
University of Chicago.

PLATE II.



186. Mo. River.

Photographs of Agar Plates
Showing
NUMBER OF COLONIES
in $\frac{1}{100}$ cubic centimeter.
Developing in Different
Water Samples.

4749a Q. State what the photographs on plate 2 represent?

A. The photographs on plate 2 are the photographs of agar plates made from samples of water collected on November 20th, 1901. They show the number of colonies in .01 of a cubic centimeter, developing in different water samples taken at cross-section at chain of rocks in the Mississipi river and also from the Missouri river at Fort Bellefontaine. They show a substantially similar condition to that obtained on October 28th, 1901, as shown in plate 1. The water from the Illinois river is much freer from colonies than the water from the Missouri river, from the Mississippi river at the intake tower and from the Missouri shore.

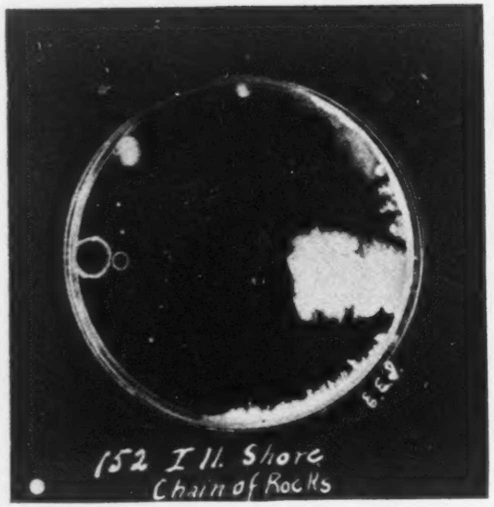
Plate 2 shows again the close similarity between the water from the Missouri river and that taken from the Mississippi river at the intake tower and shows that in the mixing of the water from the Mississippi river along the Illinois shore, that the water from the Missouri river would diminish the number of bacteria per cubic centimeter.

Q. Have you prepared another plate numbered 3?

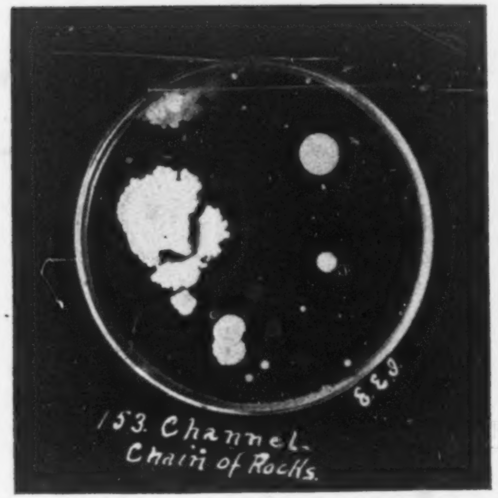
A. I have.

Q. Will you produce that plate so as to make it a part of the evidence in this case?

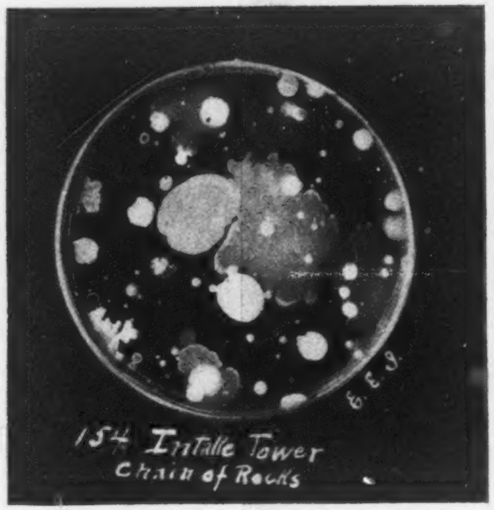
4749b A. The plate is as follows:



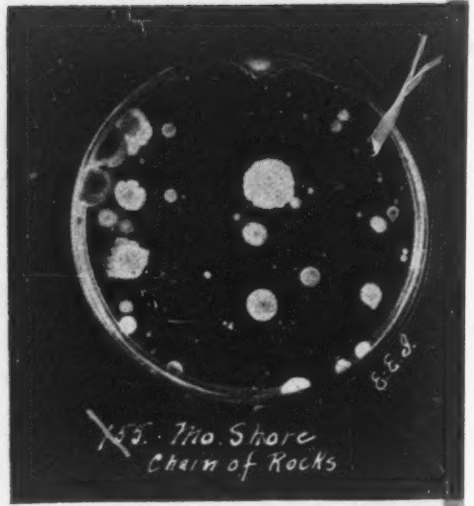
E.E.G.
152 Ill. Shore
Chain of Rocks



E.E.G.
153. Channel.
Chain of Rocks.



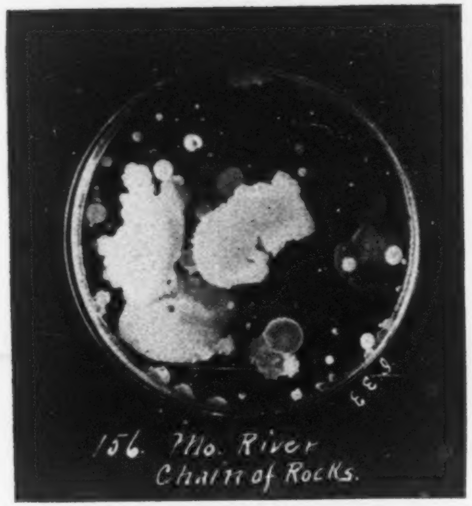
E.E.G.
154 Intake Tower
Chain of Rocks



E.E.G.
155. Mo. Shore
Chain of Rocks

Bacteriological Laboratory.
University of Chicago.

PLATE III.



E.E.G.
156. Mo. River
Chain of Rocks.

Photographs of Agar Plates
Showing
NUMBER OF COLONIES
in $\frac{1}{10}$ cubic centimeter
Developing in Different
Water Samples.

9750 Q. State what plate 3 shows?

A. Plate 3 shows five photographs of agar plates made from samples of water collected from the Mississippi river at chain of rocks on November 13th, 1901. They show the number of colonies in .01 cubic centimeter of water, developing in different samples taken in cross-section at the chain of rocks, and also from the Missouri river at Bellefontaine.

A similar condition to that shown in plates 1 and 2 is also apparent in these photographs, namely, that the water in the Mississippi river on the Illinois shore contains fewer bacteria per cubic centimeter than the water in the Missouri river or the water at the intake tower, Missouri shore. The general similarity of the photographs of samples of water from the intake tower, the Missouri river, from the Missouri shore, the Missouri river and from the Missouri river itself shows that the water entering the intake tower at this date was in a great part, if not wholly, derived from the Missouri river. These photographs show also that in case any water from the Illinois shore of the Mississippi river intermingled with the water of the Missouri river at this date it would decrease the number of colonies developing per cubic centimeter as shown in the table of averages for this cross-section at the chain of rocks during the 9751 period of 1901, which has just been introduced in evidence. These photographs are thoroughly representative of the conditions obtaining in the Mississippi river during this period. The agar plates showing this condition have been selected for reproduction because of this representative character.

MR. JEFFRIES: I move to strike out the photographic plates just introduced in evidence and made a part of the record, for the reason that the samples of water from which the analyses and plates or photographs were made, do not characterize the bacterial condition of the water at all times of the year, and for the reason that they are not representative of the bacterial content of the water at all times at the particular points in the river where the samples of water were collected, and are not representative of the bacterial condition of the water in the river at that point at the time the samples were taken as shown by different results having been obtained by other bacteriologists in analyzing companion samples of water taken at the same time and place as these in question.

And I move to strike out all that the witness has said with reference to these photographs properly character-
9752 izing and representing the bacterial condition of the water in the Mississippi river at the chain of rocks during the entire period of 1901, for the reason that they are not based upon any bacterial or scientific knowledge, but the facts so sought to be stated, and so stated by the witness can be observed by the Court in comparing the number of bacteria contained during the entire period of 1901, with the number of bacteria appearing in the samples from which the photographs were made, and I move to strike out the photographs in question for the reason that they are incompetent, irrelevant and immaterial and throw no sufficient light upon the subject at issue that can be relied upon to any credible extent, and I move to strike out all of the tables with reference to the analyses of water in the Illinois river at Grafton, and the water in the Mississippi and Missouri rivers during the period of 1901 introduced in evidence by this witness for the reason that the same is incompetent in that no sufficient foundation is laid for the introduction of the results of the analyses determined by the persons in charge of the stations at St. Louis, Peoria and Grafton, and I move to strike out the table of averages read into the record by this witness and based upon the analyses of the water at the points in question, during the year 1901, for the reason that the table of
9753 averages conceals and fails to reveal all the conditions that pertain to the waters of the river at the respective points during all times and seasons of the year.

Adjourned until 10:00 a. m., following day, Friday, December 4th, 1903.

10:00 A. M., Friday, December 4th, 1903.

9754 Continuation pursuant to adjournment.

Present, the Commissioner and same counsel representing the respective parties.

THE COMMISSIONER: Gentlemen, I have the sad duty to announce to you that I am just in receipt of a telegram from Captain R. W. Springer, announcing the death last night of his father, the Honorable William M. Springer, one of the counsel in this case.

MR. TODD: Mr. Commissioner, in view of the sad tidings which you have communicated to us in regard to the death of Judge Springer, I believe it fitting and proper as a mark of respect to his memory that the hearing of this case be adjourned. Mr. Commissioner, no man connected with this case was held in higher regard and respect than Judge Springer. I believe I voice the sentiment not only of the attorneys who are associated with him upon the side of the defense, but the sentiment of the attorneys representing the complainant. I believe that his conduct in the trial of this case has impressed upon us all the sincerity and beautiful character of the man. His acts and utterances here have appealed not only to all of the attorneys, but to the witnesses who have been called upon both sides to testify. The witnesses who have testified in this case
9755 are representatives of the highest thought and scientific
opinions, men of unquestioned integrity, lofty scientific learning, who occupy positions of high trust in our different colleges and universities, and these men have held Judge Springer in the highest respect and esteem, and in view of his sad taking off at this time, we can only express our feelings of sympathy for his loved ones that remain.

I move therefore, that this hearing be adjourned until the 28th day of December, and if the Supreme Court shall grant a continuance that then it be continued again until the 5th day of January, 1904.

MR. DRENNAN: I concur sincerely in all that Mr. Todd has said in reference to Judge Springer.

JUDGE CREA: On behalf of the State of Illinois and H. J. Hamlin, Attorney General of the State, I concur entirely with all that has been said with reference to William M. Springer.

MR. JEFFRIES: I want to assure counsel for the defense that the State of Missouri, the complainant in this cause, concurs fully in every word that has been uttered, and I want to join with him and his associates, in asking the continuance requested in this motion.

I want to say further, Mr. Commissioner, that during the time we have been engaged in taking the testimony, I, in con-

nection with counsel upon both sides of the case and in
9756 conjunction with all of the witnesses who have testified,
have not only learned to know Judge Springer, but have learned to love him. We have learned to know him not because of the particular part that he has taken in the production of the evidence here, but by his conduct we have learned to judge of the record that he has made during his life, and through his conduct here, and judging his life as we feel we have a right to do, we have learned to love him. I do not know that more could be said at this time, than the simple statement that by his conduct here, his political and private life, lead us to believe that he realized that by the golden gift of God he was given an opportunity to live but once on earth, and having but the one opportunity, he endeavored to live nobly, and by living nobly his heart was happier, his burdens lighter, and we know that the world and our people are the better for it.

THE COMMISSIONER: It seems particularly sad that Judge Springer should not have lived to complete his part in this great controversy to which he has devoted to my personal knowledge, most of his working hours for the last three years, and to which he brought at its very inception a mind trained and thoroughly qualified to take up the work which he has done. His death, however, is to me a very great personal loss. I had no better friend and no man ever had a truer one than William M. Springer.

9757 Young and old, we can ask nothing more than that when it comes to us to lay down our lives, it can be so truly said of us "He has done his part well."

The motion for continuance until the 28th of December 1903, out of respect to the memory of Judge Springer is granted.

FRANK S. BRIGHT,
Commissioner.

ADJOURNED until December 28th, 1903.

STATE OF MISSOURI,
9758 VS.
THE STATE OF ILLINOIS
and the SANITARY DISTRICT
OF CHICAGO.

Met pursuant to adjournment Monday, February 1, 1904, at 869 Rookery Building, Chicago.

PRESENT:
Frank S. Bright, Esq.,
Commissioner of the Supreme Court of the United States,
Messrs. Todd, Drennan and Crea, representing defendants.
Mr. Jeffries, representing the complainant.

9759 PROFESSOR E. O. JORDAN resumed the stand for further direct examination by Mr. Todd.

Q. Professor, did you make any determinations for colon bacilli in 1901?

A. I did.

Q. These determinations were made in the three laboratories that you have testified to as having been established at Peoria, Grafton and St. Louis?

A. Yes sir, at those three stations.

Q. What stations along the Illinois, the Mississippi and Missouri Rivers were the coli determinations made from?

A. In 1901 from the Illinois River at Averyville and Pekin; from the Illinois River above Grafton, and the Mississippi River above Grafton, from the Missouri River at Bellefontaine and from a cross section in the Mississippi River at the Chain of Rocks. At four places, the Illinois shore, mid stream, intake tower and Missouri shore.

Q. What purpose did you have in view to be subserved in making determinations for the bacillus coli communis?

A. The relative abundance of the colon bacillus in water I consider as affording the most satisfactory indication 9760 of the sanitary quality of such water. In my opinion this is the judgment of most sanitary experts at the present time. In a paper entitled "The Significance of Bacteriological methods in Sanitay Water Analysis," published from the Biological Laboratories of the Massachusetts Institute of Technology by C. E. A. Winslow and C. P. Nibecker, and printed in the Technology Quarterly, Volume 16, number 3, September, 1903 appears the following statement:

"Colon bacilli are either wanting in good waters or are so rare as not to be found in the examination of samples of one cubic centimeter; they are found in a majority of one cubic centimeters of water so polluted as to be dangerous for drinking; between these two extremes their numbers vary with the amount of pollution. Klein and Houston in England, Jordan, and Winslow and Hunnewell in America, and very recently Petruschky and Pusch in Germany have exhaustively studied the distribution of the colon bacillus with uniform results, and that the absence of this organism demonstrates the harmlessness of a water as far as bacterliology can prove it, no one would probably hesitate to acknowledge; and that when present its numbers form a trustworthy measure of its sanitary condition, the observers above quoted have proved beyond
9761 reasonable cavil."

This statement represents my own judgment in the matter as well as what is the prevailing opinion among sanitary experts generally and it is for this reason that in my studies into bacteriological conditions existing in the waters above mentioned, I have paid particular attention to the presence and relative abundance of the colon bacillus.

Q. What methods did you employ in the determination of the coli bacillus in this examination made in 1901?

A. I employed a method known as the Dextrose Fermentation Tube Method. Exhaustive comparative tests were made with the dextrose fermentation tube method, with the neutral red method, with the carbol broth method and other methods sometimes used in making this test with the result that the dextrose fermentation tube method proved the most reliable.

The method consisted in inoculating measured quantities of the water to be tested in fermentation tubes containing ordinary nutrient broth with an addition of one per cent. dextrose.

The interpretations adopted for the changes so produced were as follows:

Positive reactions, that is those indicating presence of B.

coli were regarded as those tubes showing the gas production of over twenty per cent. of the tube length; the tubes
9762 yielding on absorption with sodium hydroxide a gaseous residue appreciably in excess of the carbon dioxide observed. Negative reactions were those showing

(a) No gas production or

(b) Gas production less than ten per cent. of the tube length.

The doubtful class was made to include:

(a) Those tubes yielding only ten to twenty per cent of gas, and

(b) Those yielding more than twenty per cent, before that appreciable excess of carbon dioxide.

A series of fermentation tubes was examined in detail to determine the limits of accuracy of this method, with the result that out of sixty-three tubes examined in thirty-nine cases where the interpretation was positive typical bacillus coli communis was isolated from the tube and identified in all its biological characteristics.

In seven cases where the presumptive test yielded a positive result the bacillus coli was not isolated. This may have been and in my opinion was because the colon bacillus after producing its characteristic fermentation changes was subsequently overgrown by other forms such as the sewage streptococcus.

In nine cases where the interpretation was doubtful the colon bacillus was not isolated.

9763 In four cases where the interpretation was doubtful typical bacillus coli was isolated.

In four cases where the interpretation was negative the bacillus coli was not isolated.

It may be added that these last named cases were those showing less than ten per cent. of gas in which gas forming organisms not B. coli were isolated. In addition some twenty tubes were examined which showed growth in the closed arm but yielded no gas producing organism of any kind.

These results, in my opinion, show conclusively that where a large number of water samples are treated the error due to relying on the presumptive test alone is not unduly large.

The specific application of this method to the problem of self purification of streams depend upon ascertaining in each case the dilution at which the tests give uniformly positive and that at which it gives uniformaly negative results. This method which rests upon the determination of the relative abundance of the colon bacillus is an extremely delicate test for recent sewage pollution.

Winslow and Nibecker in the paper just referred to, on
9764 the significance of bacteriological methods in sanitary
water analyses state, on page 237, "In the second place the bacteriological methods are far more delicate than in the others. Klein showed by experiment with dilutions of sewage that the colon test was from ten to one hundred times as successful as the methods of chemical analysis."

"Studies of the self purification of streams have confirmed these conclusions on a practical scale. Thus, "in the Sudbury River it was found that while the chemical evidence of pollution persisted for six miles beyond the point of entrance the bacteria introduced could be detected for four miles further."

This latter statement refers to the study of self purification in the Sudbury River in Massachusetts carried out by A. G. Woodman, C. E. A. Winslow and P. Hansen, and published in the Technology Quarterly, Volume 15, 1902, page 105.

Q. These analyses which you have made in regard to colon—did you make any tables of the result of your analyses of the waters taken at the different stations which you have enumerated in your previous answer?

A. I did and I have these tables here.

9765 Q. Do those tables correctly tabulate the results of your
coli determinations, made during this period of investigation?

A. They do.

Q. Will you produce and read the coli tables into the record for the station at Averyville?

A. This table designated "Illinois River, Averyville, presence of bacteria of the colon group," includes a record of determinations made on daily samples collected between October 19th and December 30th, 1901, and is as follows:

9766

ILLINOIS RIVER—Averyville.
Presence of Bacteria of the Colon Group.

No. days B. Coli found	0	3	38	34
No determination made	3	72	114	54
No positive results	0	4	49	39
Per cent. positive results	0%	6%	43%	72%

9768 Q. Will you state what the table you have just read shows in regard to colon contents?

A. The table shows that during this period the colon bacillus was never found in .001 cc.

That it was but rarely found in .01 cc (4 positive out of 72 determinations).

That it was found 49 times out of 114 determinations in .1 cc and 39 times out of 54 determinations in 1.cc.

Q. Will you produce and read the coli tables into the record for the station at Pekin?

A. This table headed "Illinois-Pekin, presence of bacteria of the colon group" includes the colon determinations made daily between October 19 and December 30, 1901.

Q. Will you state what the table you are about to read shows in regard to colon contents?

A. It shows that out of 25 determinations made with .001 cc. of river water taken from the Illinois River at Pekin, the colon bacillus was found in 28 per cent. of the samples examined.

In .001 cc in 21 per cent.

In .1 cc 78 per cent.

And in all 100 per cent of the 1. cc samples.

The table is as follows:

9769

ILLINOIS RIVER—Pekin.

Q. Will you state what the table you have just read
9773 shows in regard to colon content?

A. This shows that the colon bacillus was present in 7 per cent. of the .001 cc samples.
in 5 per cent. of the .o1 cc samples.
in 13 per cent. of the .1 cc samples, and
in 30 per cent. of the 1. cc samples.

Q. Will you produce and read the coli table into the record for the station at the Mississippi River above Grafton?

A. Table number 4, headed "Mississippi River, Grafton, presence of Bacteria of the Colon Group" includes a record of colon determinations made daily from the water of the Mississippi River above Grafton between October 10 and December 24, 1901, and is as follows:

9774 MISSISSIPPI RIVER—Grafton.

Q. Will you state what the table you have just read
9776 shows in regard to colon content?

A. This shows that the colon bacillus was present in 5 per cent. of the .001 cc samples,

in 24 per cent. .1 cc samples,

38 per cent. of the 1. cc samples.

Q. Will you produce and read the coli table into the record for the station at Ft. Bellefontaine, Missouri River?

A. Table number 5, headed "Missouri River, Bellefontaine, Presence Bacteria of the Colon Group," contains the result of daily determinations made upon samples of Missouri River water between October 23 and December 17, 1901, and is as follows:

9777 MISSOURI RIVER—Bellefontaine.

Per cent. positive results	3%	19%	50%	79%	88%

Q. Will you state what the table you have just read
9778 shows in regard to colon content?

A. This shows that the colon bacillus was present:

In 19 per cent. of the .001 cc samples,
in 50 per cent. of the .01 cc samples,
in 79 per cent. of the 1. cc samples.

Q. Will you produce and read the coli table into the record for the station at the Chain of Rocks, Mississippi River?

A. These tables, numbers 6, 7, 8 and 9, contain records of the daily colon determinations made upon the water of the Mississippi River at the Chain of Rocks, in cross sections, as previously described in my testimony, viz.: at a point near the Missouri Shore, at the Intake Tower, in midstream and at a point mid way between the Illinois shore and midstream.

These tables contain records of the daily colon determinations made between October 22 and December 14, 1901, and are as follows:

9779

9783 Q. Will you state what the table you have just read shows in regard to colon content?

A. These tables show that on the Missouri shore the colon bacillus was present in 13 per cent. of the .01 c. c. sample,

In 41 per cent. of the .1c. c. sample, and,

88 per cent. of the 1. c. c. sample.

At the Intake Tower the colon bacillus was present in 20 per cent. of the .01 c. c. sample, and in

57 per cent. of the .1 c. c. sample, and

84 per cent. of the 1. c. c. sample.

In the samples taken from mid stream the colon bacillus was present in 6 per cent. of the .01 c. c. sample,

In 22 per cent. of the .1 c. c. sample,

81 per cent. of the 1. c. c. sample.

In the water of the Mississippi river at the Illinois shore the colon bacillus was present in

5 per cent. of the .01 c. c. samples,

10 per cent. of the .1 c. c. samples,

60 per cent. of the 1. c. c. samples.

Q. Did you prepare a table of summaries based upon the 9784 coli tables which you have already introduced in evidence?

A. Yes, sir, I have them here.

Q. Will you produce and read the table of summaries prepared by you from the tables of coli determinations already read in evidence?

A. Table A is as folows:

Table A.—Showing Presence of Bacteria of the Colon Group.

9786 Q. Will you state what the table you have just read in evidence shows?

A. This table shows the presence of bacteria of the colon group in the water collected from the stations just set forth.

This table shows the total number of days on which water was examined during this period and the total number of days on which bacillus coli was found.

Q. Have you made other tables of summaries besides table A?

A. I have here table B showing the presence and percentage of the bacteria of the colon group, based on the total number of determinations made?

Q. Will you produce and read table B in evidence?

A. It is as follows:

Table B.—Showing Presence of and Percentage of Bacteria of the Colon Group.

9788 Q. State what table B shows?

A. Table B shows the total number of determinations made from samples of water collected from the already specified points in the Illinois, Missouri and Mississippi rivers, together with the number of positive results and the percentage of positive results.

Q. What sanitary significance do you attach to your tables of coli determinations considered as a whole?

A. In my opinion the fate of the colon bacillus in running water furnishes a very satisfactory indication as to the degree and rate of self-purification in such water.

The fact that the colon bacillus is present in but 43 per cent. of the .1 c. c. examinations from the Illinois river at Averyville while it is present in 100 per cent. of the .1 c. c. samples taken from the Illinois river at Pekin and in only 13 per cent. of the .1 c. c. sample taken from the Illinois river at Grafton shows not only the extreme delicacy of this test for sewage pollution but shows a very considerable improvement in the sanitary quality of the water occurs between Pekin and Grafton, notwithstanding the large amount of pollution at Pekin. Comparing the condition of the water in the Mississippi river above
Grafton with that in the Illinois river above Grafton
9789 as evidenced by the colon content of these two waters, it
appears that the colon bacillus was present in 5 per cent. of the determinations made of .01 cc of water from these two places.

It may be mentioned that 117 determinations were made of the Illinois River water above Grafton and 115 of the Mississippi River water above Grafton during this period, so that the substantial agreement in percentage shown in the sanitary character of these waters during this period has a satisfactory statistical basis.

Comparing the examinations made of .1 cc of water during this same period it is shown that 24 per cent. of the samples from the Mississippi River yielded positive results while 13 per cent. of those from the Illinois River above Grafton yielded positive results.

In 1. cc of water from these two stations 38 per cent. of the samples from the Mississippi River and 30 per cent. of those from the Illinois River gave positive results.

In other words, so far as any conclusion as to the sanitary character of these waters can be drawn from the colon determinations—and I have already indicated that in my opinion and in that of sanitary experts generally, the colon test is the most delicate and satisfactory clue that we have to the sanitary condition of the water—the water of the Mississippi River above Grafton during this period was, if anything of a less
9790 wholesome character than the water of the Illinois River above Grafton.

Comparing further the colon content of the Missouri River water above Bellefontaine during this period it is shown that 19 per cent. of the .01 cc samples were positive as compared with 5 per cent. in the Illinois River at Grafton, and that 50 per cent. of the .1 cc samples were positive as compared with 13 per cent. in the Illinois River at Grafton and that 79 per cent. of the 1.cc samples were positive as compared with 30 per cent. in the Illinois River above Grafton.

Comparing the per centages of positive results obtained in the examination of 1. cc. of water in cross section at Chain of Rocks it appears that there was a smaller per centage of colon bacteria in the Mississippi River on the Illinois shore and in mid stream than at the intake tower and on the Missouri shore. This confirms the difference already noted between the colon content of the Illinois River and the Mississippi River at Grafton and that of the Missouri River at Bellefontaine. The higher colon content of the Missouri River betrayed itself in the larger number of colon bacilli found in the Mississippi River at the
9791 Intake Tower and near the Missouri shore at the Chain of Rocks.

The sanitary significance which I attach to these findings is based on what I have been able to learn by my own observation and experiments regarding the significance and relative abundance of the colon bacillus in waters of various kinds as well as that derived from an examination of the available literature on the subject and the opinions of various sanitary experts already referred to in my testimony. It may be summed up by the statement that the water from the Missouri River during this period was distinctly more dangerous and unwholesome than the water of either the Illinois or the Mississippi River at Grafton, and further that the difference between the Illinois

River above its mouth and the Mississippi River above Grafton while not great shows that on the whole the Illinois River was in a less highly polluted condition than the Mississippi.

MR. JEFFRIES:

I move to strike out the last part of the answer where the witness undertakes to form an opinion and draw a conclusion as to the sanitary condition of the water in the three respective rivers for the reason that the same is not based upon all the sanitary and the unsanitary conditions pertaining to the respective waters and ask that the opinion, if it be permitted
9792 to stand be confined solely to the tables that the witness has introduced with reference to the colon test and I move to strike out all of such tables because no proper foundation has been laid for their introduction and for the further reason that they do not represent the condition of the water in the respective rivers so far as the colon bacilli are concerned at all times of the year, and for the further reason that the number of analyses made for these two tests are so limited and indefinite as compared with the great volume of water under consideration, that the evidence is wholy immaterial and is not worthy of credit.

MR. TODD:

Professor, were those examinations made in pursuance of an agreement mutually entered into between the representatives of the complainants and the defendants?

A. I understand that they were.

MR. JEFFRIES:

I object to anything that the witness understands.

A. I will change the answer. In my opinion, yes, they were. Samples of water were taken at points designated, and on days specified by representatives of the bacteriological work undertaken by the City of St. Louis and by representa-
9793 tives of the bacteriological work undertaken in behalf of the sanitary district.

MR. JEFFRIES:

I move to strike out the question and answer for the reason that it is immaterial and move to strike out the answer because of the fact that samples of water taken, as stated by the witness, were not sufficient grounds to authorize any such conclusions as the witness has undertaken to draw from the analyses made by him from the samples of water so taken.

MR. TODD:

Does counsel deny that such an agreement was made between the Sanitary District and representatives of the complainant as to points of collection, the time of collection and the methods to be pursued in these analyses?

MR. JEFFRIES:

In answer to Mr. Todd's question I will say that I can not say that I know any such arrangement was made or that any such arrangement was not made, but, if made, it would not be binding upon the State of Missouri, because the City of St. Louis is not a party to the proceedings here, and for the further reason that if made such an agreement would not warrant
9794 or authorize this witness to draw any such conclusions as
he has undertaken to draw from the analyses alone.

MR. TODD: I want to state for the benefit of the counsel that I am not asking my question as touching upon conclusions but merely to have information as to whether when I, as representing the Sanitary District, met with the representatives from St. Louis, whether they were appearing before us in good faith as representing the State of Missouri or whether they were inpostors.

MR. JEFFRIES: I would like to ask counsel to state when and where the representatives of the State of Missouri or the City of St. Louis appeared during the hearing held by this commission.

MR. TODD:

I would like to state, for the benefit of counsel, that the gentlemen who assumed to represent the complainant in this case appeared before the Board of Trustees of the Sanitary District of Chicago, where it was mutually agreed between the Board of Trustees of the Sanitary District of Chicago and the State of Illinois, represented by the Attorney General, that certain places should be designated for the taking of samples, certain samples should be taken for analysis, and that this
9795 investigation should be conducted jointly, but that each
one could put in the results of their examinations separately as they saw fit and this is the first time it has been intimated to me that such an agreement could possibly have been made with representatives from St. Louis, not in good faith.

MR. JEFFRIES:

Well, I will state for the benefit of counsel that if any such arrangement or any such agreement was ever made between himself and persons purporting or representing themselves as representing the City of St. Louis and the State of Missouri that this is the first intimation that I ever had of any such agreement. I have heard of an agreement between sanitarians and certain witnesses in the case as to the manner in which samples of water should be taken, but who were the parties to that arrangement or agreement I have not yet been able to fully determine.

I will say further that I care nothing about it for the purpose of my objection, whether any agreement of this kind was made either with counsel for the State of Illinois or the Sanitary District of Chicago on the part of certain persons,
9796 citizens of the State of Missouri, but I do object to the
conclusions that this witness has undertaken to draw, wherein he has confined himself solely to the results of the analyses for colon bacilli determination.

MR. TODD:

Q. Professor, did you prepare any photographs?

A. I did.

Q. Photograps of what did you prepare, Professor?

A. In addition to the photographs of plates of colonies which I have already introduced in my testimony I have two plates of photographs of fermentation tubes, showing the differences in amount of gas production in fermentation tubes from samples of water taken from the Missouri River at the Chain of Rocks and from the Missouri River at Bellefontaine.

Q. Are those photographs characteristic of the samples of water which you analyzed at the points from which samples were taken from which photographs were made?

A. They are entirely so and were selected for the reason that they were thoroughly representative of the conditions existing.

Q. Will you produce plate 4 and make it a part of the record?

9797 MR. JEFFRIES: I object to the photograph being introduced in evidence for the reason that it represents one

single sample of water taken at the point in question and ca not from the very nature of things be representative of the whole volume of water or the chemical or bacterial conditions of the whole body of water passing down the river from which it was taken.

PLATE IV.

9799 Q. Will you state what plate 4 shows?

MR. JEFFRIES: I object to the witness making any statement as to what the plate shows for the same reason as stated in my objection to the introduction of the photograph and for the further reason that no chemist, bacteriologist or sanitarian can draw conclusions as to the sanitary condition of the water by the chemical or bacteriological or both analyses of only one sample of that water.

MR. TODD: I am surprised to find that counsel for the complainant did not realize the force of his objections when he placed his own witness upon the stand as by a careful study of the testimony he will find that they drew conclusions from two different samples taken from two different rivers and testified as to the sanitary condition of the water from those two samples, while this photograph is representative of a number of samples taken from the point heretofore indicated.

THE WITNESS: The upper left hand photograph, labeled "Mississippi River Chain of Rocks 144 Intake Tower, 142 Illinois shore," illustrates the difference usually obtaining between samples of water taken from the Mississippi River at the Chain of Rocks. The tubes shown in the photographs were prepared from samples of water collected on November 11, 1901, at the Intake Tower of the St. Louis waterworks and at a point in the Mississippi River half way between mid stream
9800 and the Illinois shore.

The 6 tubes in the left of the photograph show results of inoculating similar tubes with varying quantities of water, viz.: 1.cc at the extreme left (1 tube), .1 cc (2 tubes), .01 cc (2 tubes), .001 cc (2 tubes).

The photograph shows that the gas appeared in the 1. cc tube, in both of the .1 cc tubes, and in one of the .01 cc tubes. There was no gas in the .001 cc tube.

In the right of the photograph are shown the results of inoculating into the tubes the same quantities of water taken from the Mississippi River near the Illinois shore. No gas appeared in the .001 cc tube and no gas appeared in .01 cc tube, and only 1 tube of the .1 cc samples showed gas production.

Since one of the most salient characteristics of the colon bacillus is its production of gas in these fermentation tubes the photograph plainly shows what the detailed tables show on a larger scale, viz: that the colon bacillus, during this period, was not so abundant in the water of the Mississippi River near the Illinois shore as it was in the water of the Mississippi River at the intake tower of the St. Louis water works.

The upper right hand photograph headed 1-10 cc shows
9801 the results obtained by inoculating fermentation tubes on
November 22, 1901, with .1 cc of water taken in cross section at chain of rocks at the usual points, and also from the Missouri River at Bellefontaine.

It shows that no gas appeared when this quantity of water taken from the Illinois shore was inoculated into the fermentation tube while both tubes of water taken from the Missouri river and from the Mississippi River at the Missouri shore showed gas, indicating the presence of some member of the colon group.

The lower left hand photograph, labeled "Mississippi River, Chain of Rocks" 152 Illinois shore, 154 Intake, shows the result obtained by inoculating samples of water taken from the Mississippi River at the Chain of Rocks on November 13, 1901.

The same relation shown to exist in the photograph previously described obtains here also, viz.: more tubes of water from the river at the intake tower show gas than is the case with water taken from the Illinois shore.

The lower right hand photograph, labeled "Mississippi
River, Chain of Rocks" show a similar difference.
9802 Comparing the .01 cc tubes it is shown that no gas was
developed in these tubes on inoculation of samples of water from the Illinois shore and no gas in the sample of water taken from the channel while both tubes containing this quantity of water taken from the Intake Tower showed gas production.

These four photographs illustrate entirely typical conditions in the water of the Mississippi River at the Chain of Rocks and show that as a rule the water from the Missouri River and from the Missouri shore and Intake Tower of the Mississippi River and the Chain of Rocks contains the colon bacillus in larger numbers than the water of the Mississippi River along the Illinois shore.

Q. Have you a photograph known as plate 5?

A. I have. This is labeled "Photographs of fermentation tubes showing the difference in gas production, Bacteriological Department of the University of Chicago, Plate 5."

Q. Will you produce and make a part of the evidence Plate 5?

MR. JEFFRIES: I object to the introduction of plate 5 for the same reasons stated in my objection to the introduction of plate 4.

A. Plate 5 is as follows:

PLATE V.

9804 Q. Will you state what plate 5 shows?

A. Plate 5 shows photographs of a series of 30 fermentation tubes prepared from samples of water collected from the Mississippi River on November 23, 1901, in cross section at the Chain of Rocks and from the Missouri River at Bellefontaine. On the left of the photograph are the samples taken from the Mississippi River, Illinois shore; only one of these, viz.: that in which 1. cc of water was inoculated shows gas production. The same is true of the samples of water taken from the Mississippi River in the channel, although more gas was produced in this case.

The sample of water taken from the Intake Tower shows gas production, not only in the 1. cc tube but in the .1 cc tube, and in one of the .01 cc tubes.

An entirely exact correspondence is shown by sample No. 200 taken from the Mississippi River at the Missouri shore. 4 tubes showed gas production in this case also.

The Missouri River, No. 201, shows a very similar condition, except that no gas was produced in either of the .01 cc tubes.

This close correspondence between the colon content of the Missouri River and that of the Mississippi River along the Missouri shore and at the Intake Tower points in my opinion
9805 unmistakably to the conclusions that the sanitary character of these waters was very similar, and that the water flowing past the Intake Tower at the time at which these samples were collected was derived in a large part from the Missouri River rather than from the Mississippi or the Illinois.

The close agreement between the samples from the Illinois shore and the channel shows the essential uniformity of the body of water from these two sources and shows, furthermore, that from the sanitary point of view the water in this part of the river was less unwholesome less highly charged with objectionable bacteria than the water from the Missouri River or than the water in the Mississippi River at the Intake Tower.

Q. What do the photographs show, professor, as to the mixing of the waters at this point of the three rivers?

A. They show that as far as the bacterial content is concerned the water flowing along the Missouri shore and by the Intake Tower was derived in large part if not wholly from the

Missouri River while the water derived from the Illinois River clings to the Illinois shore and mixes little, if any, with the water of the Missouri.

Q. What is the character of the different waters?

A. The character of these waters during this period as 9806 shown by the colon examinations and as set forth in the tables and illustrated by the photographs is quite different. The colon content of the Missouri River is markedly higher than that of either the Illinois or the Mississippi River at Grafton, and from this I infer that during this period the Missouri River was more highly charged with dangerous bacteria and was distinctly less safe than the water of the Illinois River.

Under these conditions the effect of any mixture of the Illinois River water with the Missouri River water at the Intake Tower of the St. Louis water works would therefore tend to diminish the colon content of the water at that point, thereby rendering it less dangerous for human use. Such mixing of the Illinois and Missouri waters as took place would hence improve the conditions existing during this period in the Mississippi River at the Intake Tower.

Q. What were the stages of the water at the time the photographs were taken and the colon determinations were made?

A. Throughout this period, in the latter part of 1901, the water was low in the three rivers, the Illinois, the Mississippi and the Missouri.

9807 A. The exact figures of the height of the water are given in the detailed tables embodying the colony counts already submitted.

MR. TODD: Professor, Mr. Allen Hazen, on page 4530 of the record, was asked this question "when the mixing begins at the mouth of the Illinois River, by the time it gets to the mouth of the Missouri River, is that mixing complete" and he answered "I do not think it is absolutely complete. It is approximately so; more so at low water than at high water." What do your bacterial analyses show as to whether there is more mixing of these waters at low water than at high water.

MR. JEFFRIES: I object to the question as improper and made for the purpose of discrediting the testimony of Mr. Hazen and contradicting his testimony.

MR. TODD: In reply to counsel I submit that the very purpose included in his objection is correct and a legitimate inference to be drawn from the question and perfectly proper as a matter of evidence.

A. I may state in reply that in my opinion the total number of bacteria in the water at the Intake Tower and near the Missouri shore at the Chain of Rocks as well as the number of colon bacteria in the water at these points shows conclu-
9808 sively that during this period of low water, the water
collected at these two stations was almost wholly if not altogether Missouri River water and was mixed little, if any, with the water from the Illinois. If it be true, therefore, that mixing is more complete at low water than at high water it will certainly follow that the amount of Illinois River water present in the Mississippi at these two points at high water stages must be exceedingly small.

Q. What analyses did you make for species determination?

A. I made an extended examination of species of bacteria taken from the river water at the three stations already described.

Q. That includes the six points?

A. Yes sir. This examination continued through the fall of 1901 and included the study of bacteria found in the samples of water from all the collecting stations.

Q. What methods did you employ in your species determination?

A. The organisms studied in this work were isolated from four different kinds of culture media: (1) from 48 hours gelatine plates, incubated at 20 degrees Centigrade; (2) from 48 hour old dextrose broth fermentation tubes, incubated at 37 degrees; (3) from litmus lactose agar plates 35 degrees
9809 Centigrade, after passage through carbol broth at 37
degrees; (4) from neutral red broth at 37 degrees centigrade. In this way 543 cultures were isolated, studied in great detail and classified.

Q. Will you please read the table of species determination?

A. Yes sir, it is as follows:

Table II.

[1] Two cultures of the red chromogenic group are without data as to place or mode of isolation.

9811 Q. What sanitary significance do you attach to the species determination made by you?

A. This detailed study of species shows that on the whole those forms regarded by bacteriologists as characteristic of sewage pollution are found more abundantly in the water of the Illinois river at Pekin than elsewhere. The Streptococcus forms which are believed by some to be specially characteristic of recent sewage pollution were found in four cases only, viz.: two in the Illinois River at Pekin and two in the Mississippi River near the Missouri shore. The results as a whole confirm the deductions drawn from the study of the colon tables.

ADJOURNED until 10 A. M., Feb. 2nd, 1904.

9812 10:00 A. M., Tuesday, February 2, 1904. Continuation pursuant to adjournment. Present, the Commissioner and same counsel representing the respective parties.

PROF. EDWIN O. JORDAN,

resumed the stand for further direct examination by Mr. Todd and testified as follows:

Q. Do you know whether it is the usual practice in this country among analysts to make daily and hourly determinations of a river water for a long period of time in order to determine the sanitary quality of such water?

A. Reference to some of the recent studies of river water that have been made in this country shows that opinions have been formed and judgments passed on the sanitary character of river water on a smaller number of determinations than would be involved in hourly or even daily examinations.

9813 Thus I find in the report on water purification investigations carried out under the direction of Mr. G. W. Fuller, in behalf of the sewage and water board of New Orleans, Louisiana, the report being published in 1903, a series of tables showing the turbidity, alkalinity and chlorine contained in the Mississippi River water from October 1, 1900 to December 15, 1900 (page 38).

I also find a series of tables showing the composition of the Mississippi River water as determined by its examinations between December 10, 1900 and August 17, 1901.

In another recent investigation of the composition of river water contained in the report of the Filtration Commission of Pittsburg, Pennsylvania, printed in 1889, I find a series of investigations conducted under the supervision of Mr. Allen Hazen who, I believe, has already testified in this case. In Appendix Number 2 of this report, I find the statement "It was desired especially to learn about the character of water obtained from various cribs in the Alleghany river."

9814 In the next paragraph the statement appears: "The samples of the Alleghany River at Brilliant were collected about once a week from the beginning of the work until about March 1, 1898. For the next three months samples were collected twice a week and after June 1, 1898, samples were again collected once a week until the close of the experiments."

From what I know of the work of Mr. Fuller and Mr. Hazen I infer that these gentlemen, who have had large experience in undertakings of this character, would not have had these examinations of river water carried out under their direction at daily and weekly intervals during portions of the calendar year if they had not believed that such determinations actually give a basis for a fairly satisfactory judgment of the character of a river water. Mr. Fuller's examinations at Louisville and at Cincinnati, while extending over a longer period, are substantially of the same character as those in the later investigations.

In European countries, so far as I know, no extended examinations of river water, based on daily and weekly analyses, have been made, which cover so long a period of time as those that have been made in this case.

It is, therefore, my opinion that the usual practice of those experts having to do with the examination of river waters
9815 in this country is based on the belief that an adequate opinion as to the character of the water can be formed by examinations made at intervals as frequent and during periods as long as those indicated in the instances just cited.

MR. JEFFRIES: I move to strike out all the witness said with reference to the instances which he has just cited and all that the witness has read from the reports on the subject, for the reason that the same is not responsive to the question.

Q. What period of time have your own analyses covered throughout this investigation?

A. The examinations which I have made in behalf of the Sanitary District of Chicago cover two periods, the first, one of weekly examinations extending from about the first of May, 1899, to the first of July, 1900. During this period the regular weekly examinations were supplemented by daily and in some instances hourly examinations of the river waters at several points. The second period includes daily examinations made between about the first of November, 1901, to about the first of January, 1902. In all, the examinations that I have
9816 made cover a period of one year and five months.

Q. In your opinion is it possible to pass a competent judgment upon the waters of the Illinois, Mississippi and Missouri Rivers on the basis of the analyses you have submitted in your testimony?

A. It is decidedly my opinion that such is the case. The analytical data, chemical and bacterial, that I have secured by these weekly, daily and hourly determinations, extend over a sufficient interval of time and include sufficiently varying conditions to permit of a satisfactory judgment being rendered as to the general character of the waters dealt with. The separate analyses number many thousands and the results embody the experience gleaned from a study of high water and low water conditions, of summer and winter temperature, and of varying climatic and meteorological factors. It is my judgment that taking into consideration the analyses made concurrently by Professors Palmer, Long, Zeit, Gehrmann and Burrill no such extensive and exhaustive study of river water, in connection with the problem of self purification of streams, has ever been made anywhere in the world as that carried out during this period.

9817 Q. Professor, from your survey of the Missouri and Illinois Rivers, as evidenced by your various analyses heretofore testified to in this case, will you state how the Missouri River compares with the Illinois River before the 17th day of January, 1900, as to its sanitary quality?

MR. JEFFRIES: I object to that as immaterial.

A. During this period the condition of the Missouri River as compared with that of the Illinois River above Grafton was less satisfactory from the sanitary point of view, and was distinctly inferior to the Illinois River at Averyville.

MR. JEFFRIES: I move to strike out the answer as being misleading, indefinite and not responsive.

Q. How did the Illinois River compare with the Missouri River after January 17, 1900?

A. The relative character of the two rivers was not materially different from the 17th of January, 1900, to the first of July, 1900. That is to say, the Missouri River water was more objectionable from a sanitary standpoint than the water of the Illinois River at its mouth or at Averyville.

Q. How did the Illinois River compare with the Missouri River for the period 1901?

A. During the period October-December, 1901, when 9818 daily examinations were made and a large number of results obtained, the sanitary quality of the Missouri River water was, in my opinion, distinctly inferior to the Illinois River water at its mouth and at Averyville, as shown especially by the colon determinations.

Q. What sanitary significance do you attach to your chemical and bacterial analyses including the colon tests, colony counts and species determinations heretofore introduced into evidence, as evidenced by the tables and charts and photographs already introduced by you?

A. Taking into consideration all the analytical data that I have obtained throughout the seventeen months covered by the investigations, I conclude that one of the most remarkable facts, if not the most remarkable, is the entire concurrence of the results derived from the chemical and the various bacterial determinations. The amount and rate of nitrification in the water of the Illinois River at various points along its course, as shown by the tables of chemical analyses, are in line with what the experience of water analysts has shown to accompany a real purification. The large amount of organic matter present in the upper stretches of the Illinois River is oxidized during its passage down stream, and before Averyville is reached 9819 the nitrification of this organic matter has progressed practically to completion.

On the bacterial side, the evidence is wholly confirmatory of this improvement in the quality of the Illinois River water. The enormous number of bacteria poured into the Illinois River in its upper stretches, as shown by the number of bacteria present

in the Illinois River at Lockport and Joliet, is greatly diminished in a flow of less than one hundred miles. Under certain conditions even, and at certain periods of the year, the Illinois River becomes nearly free from the great mass of sewage bacteria with which it was originally laden in as short a distance as 24 miles, as evidenced by the observations between Morris and Ottawa, already introduced. Both at Averyville and above Grafton the bacterial composition of the Illinois River water is about the same as that of tributary streams and as that of the Mississippi River just above Grafton. The colon contents of the Illinois River water is in my opinion, especially significant from a sanitary point of view, and affords evidence in entire harmony with the conclusions derived from the chemical examinations and from the number of bacteria of all kinds shown to be present in these waters. The colon bacteria which are found in great abundance in the waters of the drainage canal and in the
9820 upper stretches of the river practically disappear before
Averyville is reached.

It is clear from the data that I have presented that the water of the Illinois River undergoes a real and very considerable purification. The colon bacteria which are shown to be present in large numbers in Chicago sewage disappear almost completely in less than 150 miles flow. At the mouth of the Illinois River, despite the enormous initial pollution and the very large secondary pollution at Peoria, the number of colon bacteria is certainly no greater than the number in the Mississippi River at this point, and not as large as the number in the Missouri River at Bellefontaine. Since all investigators are agreed that the colon bacillus is more hardy than its relative, the typhoid bacillus, and can live in water for a longer time there is every reason for supposing that the latter microbe dies out with at least the same rapidity. If it be true, as I firmly believe to be the case, that the fate of the colon bacillus in running water furnishes the most satisfactory indication we can secure at present of the continuance of vitality of the typhoid bacillus, there can be no hesitation as to the conclusion to be drawn from this investigation. Since this biological relative of the typhoid bacil-
9821 lus perishes speedily and in large numbers in the course
of the Illinois River, it is my opinion that the typhoid

bacillus itself can not long survive exposure to the same conditions.

Q. Have you made a special study of bacteria?

A. Yes, that has been my main occupation for some fifteen years.

Q. What are bacteria?

A. Bacteria are the smallest and simplest of all living things. They are one-celled organisms, closely related to the lowest forms of plant life.

Q. How are they classified and distinguished?

A. The most general method of classifying bacteria is based on certain differences in form. Three forms of bacteria are generally recognized. The sphere, the rod and the twisted or spiral form. These three kinds of bacteria may be distinguished by the microscope. The spherical bacteria are known as the coccus or the micrococcus forms, the rod-shaped bacteria as the bacillus form, and the corkscrew-shaped forms as the spirillum or vibrio type. The subdivisions of these three groups are distinguished by bacteriologists at the present time by certain structural and functional characteristics. Thus the
9822 position and numbers of the organs of locomotion, the
method of spore formation and other qualities have been used for distinguishing and classifying the various species and varieties. Especial importance has been laid upon the chemical changes brought about by bacteria in the substances in which they grow. Thus, the liquefaction of gelatin, the production of pigment, and the formation of acid or alkali in various food substances are used for distinguishing and differentiating the various kinds of bacteria. The sure and certain differentiation of the numerous species and varieties of these microbes has become a matter involving much time and special skill, and demands special training and experience for its satisfactory accomplishment.

Q. How are they distributed?

A. They are distributed in nature very widely; being found in air, in water and in soil, upon the bodies of living plants and animals and, in short, wherever they can find suitable conditions for growth and multiplication. They are found in large numbers where suitable organic matter is present which serves them as food and enables them to thrive and multiply.

Where the conditions are not suitable owing to improper temperature, to lack of moisture or to insufficiency of food, they are not found so abundantly, and if found at all are likely to be in a dormant rather than an active condition.

9823 Q. What are the characteristics of the bacteria peculiar to waters?

A. Certain species of bacteria are commonly found in pure, unpolluted waters, such as the waters of deep wells, of springs in sparsely inhabited districts, and of lakes and ponds into which no sewage enters. These harmless water bacteria are different from the bacteria found in waters contaminated with organic matters of animal origin, and there is no reason to suspect these water bacteria of possessing any dangerous qualities. Only those bacteria derived from the bodies of human beings or of the higher animals have any special sanitary importance. The so-called water bacteria as a class are simply harmless saprophytes living upon the small amounts of organic matter ordinarily present in pure waters.

Q. Will you distinguish between the so-called saprophytes and parasites?

A. A saprophyte (from Greek corpse-plant) is a name usually applied to those forms of plant life that feed upon lifeless organic matters such as are contained in the dead bodies of plants and animals. Parasites on the other hand are
9824 those forms of life that are able to invade the bodies of some other organism and to obtain their nourishment from the tissues of the host-animal or host-plant. Some bacteria are exclusively saprophytic so far as known; that is, they grow only on lifeless matter and when introduced into the bodies of animals or plants are not able to grow and multiply there.

Some bacteria on the other hand are strict or almost strict parasites. That is, they find the most favorable conditions for their existence in or upon the live bodies of animals or plants, and grow feebly, if at all, outside of the bodies of their respective hosts.

The bacillus of leprosy is a familiar instance of a strict parasite. While it multiplies in the tissues of man it has not yet been cultivated outside of the human body. It is a parasite strictly adapted to the human host.

. Most bacteria, however, are able to live either as saprophytes or as parasites.

Q. Will you distinguish between non-pathogenic and pathogenic bacteria?

A. The pathogenic bacteria are those bacteria that are
9825 able by their presence and products to bring about morbid changes within the bodies of plants or animals. No sharp line can be drawn between pathogenic and non-pathogenic bacteria any more than between saprophytes and parasites. No bacterium is pathogenic for all animals under all conditions. Thus the typhoid bacillus which lives and produces disease in the body of man dies out speedily in the intestinal tract of other higher animals without producing any injurious effect. What is known as the virulence of a bacterium, that is to say, its power to produce disease or morbid changes, varies considerably. A bacterium which under certain conditions is pathogenic for man or other animals may lose its virulence or pathogenic power by long sojourn under natural conditions outside of the animal body. It is well known for example that the tubercle bacillus when freshly isolated from sputum or the animal body is more virulent than when it has been kept under cultivation on lifeless organic matter outside of the body for a considerable period. In other words, it loses its virulence outside of the animal body. The same thing is known to be true of other kinds of pathogenic bacteria. Pathogenicity then
9826 is relative, not an absolute term.

Q. What are the known bacteria pathogenic to man?

A. The list is quite a long one. It includes the typhoid bacillus, the anthrax bacillus, the diphtheria bacillus, the tetanus bacillus, the cholera spirillum, the micrococci causing blood poisoning, septicemia and erysipelas, the bacillus of tuberculosis, the micrococcus of pneumonia and some others.

Q. What pathogenic bacteria are water-borne and find their way into the human body in drinking water?

A. In countries in the temperate zone the typhoid bacillus and its near relative the paratyphoid bacillus are those most commonly entering the body by means of infected drinking water.

It is probable that some members of the group of dysentery bacilli also enter the body in this way.

The cholera spirillum is also commonly conveyed by drinking water in countries where Asiatic cholera is prevalent.

These two diseases, cholera and typhoid, are by far the most important of the water-borne infectious diseases.

Q. What is the bacillus prodigiosus?

A. The bacillus prodigiosus is a name applied to a species of bacterium, or perhaps a group of species, characterized among other things by the production of a red pigment. The group has other well defined biological properties.

9827 Q. What are its characteristics and life history?

A. It is a bacillus with a diameter less than one micron. It is motile, forms no spores, produces turbidity in nutrient broth but no pellicle on the surface, liquefies gelatin rapidly, grows upon potato luxuriantly; grows in the closed arm of the fermentation tube; grows both at body temperature (37°C.) and at room temperature. It does not produce its pigment when grown at body temperature. It is a facultative anaerobe. Liquefies casein and blood serum. Produces gas in dextrose and saccharose broth, but not in lactose. This gas is carbon dioxide and is wholly absorbed by sodium hydro-oxide. It reduces nitrate; does not produce indol; curdles milk with an acid reaction. No fecal odor is produced. Chromogenesis at ordinary temperatures is marked. Some varieties are non-pathogenic for mice, rabbits and guinea pigs, but other varieties have a very marked pathogenic power.

Q. Is it found in river water?

A. Yes, it has been found in the water of rivers and in other bodies of water in various parts of the world.

Q. Have you found it in the waters of the Illinois River?

A. On November 6, 1899, I isolated from the water of 9828 the Illinois River collected at Morris an organism which in all the characters I have described resembles exactly the bacillus prodigiosus.

I have here a sheet of species description in which the biological characteristics of three cultures of bacillus prodigiosus obtained respectively from the University of Michigan Bacteriological Laboratory, from Yale University, and from the Ontario Board of Health, are tabulated. This shows that the characteristics of these three organisms, were similar. The organism isolated from the water of the Illinois River just above Morris on November 6, 1899, possesses all the characters manifested by these three specimens of bacillus prodigiosus and it is in my opinion a member of that group.

Q. Did you find any organism resembling the prodigiosus in the water of the Illinois aside from the one you have already spoken about?

A. Yes. In addition to this form that I have identified as bacillus prodigiosus I found on several occasions organisms which resembled the bacillus prodigiosus very closely, and might on superficial examination be mistaken for it.

Q. In what respect did the organisms resembling the
9829 prodigiosus differ from them?

A. One of these labeled B 210 (a) was isolated from a sample of water taken from the Mississippi River near the Missouri shore near the Chain of Rocks November 16, 1901. It produced red pigment just as the typical bacillus prodigiosus did and on this ground might have been mistaken for it. It did not, however, produce any gas in dextrose broth. It did not liquefy blood serum and did not curdle milk, three very important respects in which this organism differs from the true bacillus prodigiosus type.

Q. Have you charted out upon the diagram alongside the prodigiosus from the University of Michigan, Yale University, and the Ontario Board of Health the one which you separated from the Illinois River at Morris on November 6, 1899.

A. Yes, I have the tables showing these five cultures in comparative form.

Q. What is the significance of the plus sign and the minus sign on the table which you have prepared?

A. The plus sign indicates that the characteristic appearing in the printed form was found upon investigation of the organism concerned. Thus: a plus sign under the head of
9830 "blood-serum" indicates that the organism liquefies
blood serum, and the minus sign under the same head indicates that it did not liquefy blood serum. The same is true

of the caption "gas production in dextrose broth." The same is true also of the signs under the head of "curdling of milk," and so on.

Q. Will you read the table including these five organisms into the record?

A. It is as follows:

9831

BACTERIOLOGICAL LABORATORY,

ADJOURNED until 2 p. m. Thursday, February 2, 1904.

9832 2:00 P. M., Tuesday, February 2, 1904. Continuation pursuant to adjournment. Present, the Commissioner and same counsel representing the respective parties.

PROF. EDWIN O. JORDAN

resumed the stand for further direct examination by Mr. Todd, and testified as follows:

Q. Professor, did you find, during your analyses of the water of the Illinois River, Mississippi and Missouri Rivers any organisms that resemble prodigiosus, other than the one you have just described?

A. On several occasions we have isolated from the water of the Illinois and Mississipyi Rivers organisms which in many particulars, especially in regard to pigment production, resemble very closely the typical bacillus prodigiosus. These organisms differ oftentimes in very slight degree from the true prodigiosus type. The differences consist, for the most part, in variations in their actions upon milk, gelatin, casein and blood serum and in their action upon the different sugars. Any examination of these organisms, other than a searching and detailed one, might lead to their being mistaken for the true prodigiosus type. 9833

Q. Professor, have you read the testimony of Mr. Ravold wherein he detailed the result of what is known as his prodigiosus experiment?

A. Yes sir, I have read this testimony as it appears in the record of this case.

Q. What importance, as a bacteriologist, do you attach to the value of that experiment as given in the record of the evidence in this case?

MR. JEFFRIES: I object to the witness making any statement as to the value or weight to be placed upon the testimony of Dr. Ravold, that being a question for the court to determine. I object to the question because it is incompetent and immaterial.

A. It seems to me to constitute a demonstration of the power of self purification in streams, from the fact that along the upper collecting stations in the Illinois River this organism was not recovered, although frequent examinations were made of the water at these points and although, according to the testimony, prodigious numbers of this organism were introduced into the water of the drainage canal.

As regards the finding of a few individuals in the water of the Mississippi River, assumed to be of the same variety
9834 as that introduced, I can only say that the identification does not appear from the records to be altogether complete. And, furthermore, assuming that the organisms recovered from the Mississippi River were actually those introduced in the drainage canal, the appearance of so small a number would not in itself be significant. This is true especially since organisms belonging to this prodigiosus group, as has been shown, are sometimes found in the water of these rivers and are saprophytic forms which are evidently rather easily habituated to aquatic life.

Q. Assume that 107 barrels of 40 gallons each of the culture of bacillus prodigiosus, consisting of one hundred million billion to a cubic centimeter, as contained in said barrels, was deposited in the Chicago Drainage Canal at the town of Lamonte, on the afternoon and evening of the 6th of November, A. D., 1901, during a period of from four to eight hours. Assume further that immediately after the said barrels were emptied into the Drainage Canal, the laboratories established at Lockport, Joliet, Peoria, Grafton, on the Illinois River, and the Intake Tower of the St. Louis water works, Chain of Rocks, were notified and that samples were collected at each of these places every hour of the day and night for the purpose of bacterial analyses,
9835 for the ascertainment of this bacillus prodigiosus, and assume that at Lockport these hourly samples taken day and night, were taken from November 7th to November 25th, a period of 18 days, the total number of samples taken being 432. Assume that at Joliet these hourly samples taken day and night, were taken from November 7th to November 25th, a period of eighteen days, the total number of samples being 432. Assume that at Peoria these daily samples, taken day and night, from November 8th to November 30th, a period of 22 days, amounted to a total of 528 samples. Assume that at Grafton these hourly samples were taken day and night from November 12th to December 15th, a period of 33 days, the total number amounting to 792 of which 384 were analyzed by Dr. Ravold.

Assume that the total number of samples taken hourly, day and night, at the Chain of Rocks were 720. Assume that at the laboratory tap these hourly samples taken day and night from November 20th to March 1, 1902, a period of 100 days, amounted to a total of 2400. Assume that the total number of samples analyzed at the different points for the period above mentioned was 5304. Assume further that on December 4th at 8:45 one bacterium bacillus prodigiosus was found at Intake Tower at Chain of Rocks. Assume that on December 5th at 9 A. M. 1 bacillus prodigiosus was found at the Intake Tower, Chain of Rocks. Assume that on December 8th, at midnight, 1 bacillus prodigiosus was found at the Intake Tower, chain of
9836 rocks. Assume that on December 6th, at 8 A. M., at Grafton, 1 bacillus prodigiosus was found. Assume that on December 7th, at midnight, at Grafton, 1 bacillus prodigiosus was found, and assume further that these five organisms were all the organisms of prodigiosus that were found in the examinations made from Lockport to the Intake Tower at the Chain of Rocks and the laboratory tap in the City of St. Louis, which were made during the progress of this investigation, as hereinbefore set forth, and at no time was there more than one single bacterium found at each of these places. Assuming all of the facts as hereinbefore stated to be true, what is your opinion as a bacteriologist as to the value of this experiment as indicating the possible longevity of an infecting bacillus as measured by the longevity of a bacillus prodigiosus or the possibility that a typhoid bacillus entering the drainage canal from the sewers of Chicago would survive the journey down the Illinois River and Mississippi River to the Intake Tower at the Chain of Rocks at St. Louis, based upon all the facts contained in the foregoing hypothetical question?

A. In my opinion this experiment sheds a certain amount of light on the probable longevity of a typhoid bacillus
9837 under the conditions as stated. This is true for the reason that the relatively insignificant findings of bacillus prodigiosus, assuming identification to be correct, indicate that this organism, while in a fairly hardy saprophytic form, does not live long in the river water, and that the typhoid bacillus, which is beyond doubt a more highly specialized parasitic form than bacillus prodigiosus, would not survive as long as the lat-

ter. The experiment, in my judgment, affords strong confirmation of the evidence already derived from a study of the death rate among colon bacilli in the water of the Illinois River. Since bacillus prodigiosus dies off so speedily and in such large numbers, the typhoid bacillus would be less likely to survive exposure to these same conditions.

Q. Will you please give the characteristics and pathological significance of the cholera germ?

A. The cholera germ belongs to the group of spirally twisted bacteria, known as the spirilla. It grows luxuriantly upon our ordinary culture media and liquefies gelatin very rapidly. It is actively motile and forms no spores. It usually finds its way into the human body by way of the alimentary tract, being taken in either in drinking water or by means of contaminated food, such as raw vegetables, fruits, etc. It produces violent fermentation of the intestinal contents and probably
9838 generates powerful toxins or poisonous substances, capable of injuring the body cells. The absorption of these toxins into the body gives rise to many of the general symptoms of Asiatic cholera and if the poisoning is sufficiently intense the infection may result in death. The evidence that the cholera spirillum is the cause of Asiatic cholera in man is convincing and complete. Cases of laboratory cholera have been known to occur among persons working in bacteriological laboratories at a time when no cholera was present in the city or town in which these laboratories were located. Infection in these cases could have come about only through some break in the chain of laboratory precautions and in several of these cases it has been shown that such neglect or carelessness occurred. These cases of laboratory cholera among persons working with the cholera spirillum afford sufficient proof that this germ in pure culture is capable of causing the typical symptoms of the disease, in such intensity even that the outcome may be fatal.

Q. Will you give the characteristics and pathological significance of the tetanus germ?

A. The tetanus bacillus belongs to the class of strict
9839 anaerobes, that is to say it will not grow in the presence of ordinary atmospheric oxygen, but in order for it to thrive free oxygen must be absent from its surroundings. Like

other anaerobes it is spore producing. Under anaerobic conditions it will grow upon the ordinary culture media, such as glucose agar and glucose gelatin. It is usually introduced into the body through some deep wound. It does not, so far as known, infect human beings when taken into the normal ailmentary tract but must find its way into the tissues. It does not spread far from the seat of inoculation but produces a very powerful toxin at the point of growth. The diffusion of this toxin throughout the body, affecting particularly the nervous system, causes the symptoms and lesions peculiar to the malady known as lockjaw or tetanus. The most common form of tetanus in this country at the present time is the so-called Fourth of July tetanus which comes from gunshot wounds, wounds with the toy pistol and similar injuries which result from the forcing into the deep tissue layers a mass of earth or other organic material containing tetanus bacilli or their spores.

Q. Is the tetanus germ a water borne germ?

A. I know of no instance where a case of tetanus has 9840 been traced to water borne infection. The germ is common in street dust, finding it's way there probably from the droppings of horses in which it is usually present in considerable abundance.

Q. Will you give the characteristics and pathological significance of the anthrax germ?

A. The anthrax bacillus is one of the longest known and best studied of pathogenic bacilli. It is a spore forming aerobic bacillus and grows readily upon our culture media. The disease known as anthrax or splenic fever is primarily a disease of cattle and sheep and is sometimes transmitted from them to man, the ordinary modes of transmission being by cutaneous infection through some wound or abrasion, or by inhalation of the spores of anthrax bacilli which may be dislodged into the air from the hides or fleece of infected animals. The affection known in England as wool sorter's disease is the pulmonary form of anthrax due to inhalation of the spores. Cattle are infected by grazing in pastures that have become infected from the presence of diseased animals or where the carcasses of animals dying from anthrax have been superficially interred. The disease in man is not a common one.

Q. Is this germ a water borne organism?

9841 A. There are a few cases on record where the refuse from tanneries has been washed into stream and deposited on fields; and cattle grazing on these fields have been known to become infected. There are also a few cases where the water of a well has become infected in this way and has caused disease among cattle. So far as man is concerned anthrax is not, properly speaking, a water borne disease since infection from this source, if it has ever occurred, is extremely rare.

Q. Will you give the characteristics and pathological significance of the bacillus enteritidis sporogenes?

A. This organism is more commonly known as bacillus aerogenes capsucatus. It is a spore forming anaerobe and is widely distributed, being found in street dust, in sewage, in manured soil and in similar situations. It is found in the contents of the healthy human intestine. This bacillus has been supposed by Klein and some other writers to have some pathogenic property for man. Taken into the human alimentary tract, however, as has been shown by Glynn ((Thompson-Yates Laboratory Report, 1901, Volume 3, Part 2, Page 131) is seems to be harmless. This might, indeed, be inferred from the fact that this bacillus occurs in healthy human evacuations.

9842 Glynn, in the investigation cited, partook of portions of the curd of milk in which this organism was numerous and suffered no ill effects, showing that when taken in this way it can not be called a pathogenic microbe. Inoculated into the circulation of guinea pigs, however, the organism produces pathological changes and death. It appears sometimes when introduced through wounds into the body of man to have some pathogenic properties, producing, oftentimes, accumulations of gas in the tissues and internal organs.

Q. When this germ enters the human system through drinking water will it produce disease?

A. Not so far as is known. The evidence indicates quite the reverse. The experience of Glynn, who, as just described, swallowed large numbers of these bacilli, without suffering any ill effect, shows that this is the case. The mere fact that this bacillus is found in the evacuations of patients suffering from diarrhoea is no proof of its casual relationship with their condition, since the same organism is found in the dejecta of perfectly healthy persons.

9843 Q. Will you give the characteristics and pathological significance of the dysentery bacillus?

A. The dysentery bacillus is a member of the colon typhoid group of organisms and is very closely related to the typhoid bacillus, being distinguished from it by its lack of motility and by its reaction to the serum of dysentery patients. There appear to be several varieties of the dysentery bacillus differing slightly one from another one. The modes of infection with the dysentery bacillus are probably very similar to those in the case of the typhoid bacillus.

Q. Have you made any special study of the typhoid germ?

A. Yes sir, I have on various occasions given rather particular attention to the characteristics of the typhoid bacillus, to the modes of infection with this organism, to its longevity in water and to its other relations with human pathology.

Q. Will you give the characteristics and pathological significance of the typhoid germ?

A. The typhoid bacillus is an actively motile non-spore forming organism. It grows readily upon gelatin, upon potato, in milk, in broth and the other ordinary culture media of the laboratory. It does not liquefy gelatin. It does not curdle
9844 milk although producing a slight acidity in milk which may be transient or may persist permanently. Some varieties of typhoid bacilli produce alkali in milk which may obliterate the original acidity. It does not form gas in dextrose broth although it ferments the dextrose with the production of acid. Upon potato most varieties produce the so called invisible film, a delicate thin growth covering the surface of the potato and so nearly the same color of the potato as to be under most conditions almost invisible.

The typhoid bacillus usually finds its way into the human body through the alimentary tract, being swallowed with infected drinking water or infected food. The bacilli, although invading the body through the alimentary tract, do not remain confined to this location but may spread through the body and be found in the blood, in the spleen and in the internal organs generally. There are some resemblances between infection with the typhoid bacillus and with the cholera spirillum, the toxins produced by the two organisms being not dissimilar, and immunity to these two diseases appearing to rest upon the same biological foundation.

Q. Where are typhoid germs found?

9845 A. Typhoid germs may be found either in the body of the patient or in the discharge from the body of such patient or in waters or soil infected with such discharges. The clothes and bedding of the patient may also become contaminated with the typhoid bacillus unless proper measures of infection are resorted to.

Q. What germs does it resemble?

A. The typhoid bacillus is a member of the so called colon typhoid group of organisms. This is a very large group of bacteria, containing many varieties or species. The colon typhoid group includes bacillus coli communis and its allies, the typhoid bacillus, the paratyphoid bacillus, the desentery bacillus, the hog cholera bacillus, bacilli found in certain cases of meat poisoning, bacilluspsitacosis and other micro organism of more or less pronounced pathogenicity.

Q. Is it related to the colon bacillus, and if so in what way?

A. It is related to the colon bacillus in being a member of this large colon typhoid group. It differs from the colon in being less vigorous. Many of the positive biological qualities of the colon bacillus are represented by negative charac-
9846 teristics of the typhoid germ. Thus, the colon bacillus ferments dextrose, with gas production, curdles milk and produces indol while the typhoid bacillus does not ferment dextrose with gas production, does not produce indol and does not curdle milk. I have already shown that as regards longevity in water, resistance to freezing, to drying and other adverse conditions of life the colon bacillus is a more hardy organism than the typhoid bacillus. The two microbes are, however, biologically very closely related.

Q. What methods can be employed for differentiating and identifying typhoid bacillus?

A. The typhoid bacillus can be differentiated from other members of the colon typhoid group by these qualities that I have just enumerated, viz.: absence of gas production in dextrose broth, failure to curdle milk or to produce any very large amount of alkalinity in milk and especially by the so called serum reaction which enables an investigator to differentiate the typhoid bacillus with certainty from the dysentery bacillus, perhaps its nearest relative in the colon typhoid group. The serum test is generally regarded as a final and precise criterion of the authenticity of a given culture. This test is based on the fact that the blood of an animal such as a rabbit or guinea pig which has been inoculated with the culture of a genuine typhoid 9847 bacillus becomes capable of clumping or agglutinating other strains of typhoid bacilli, irrespective of their sources. By applying serum from an animal that has been inoculated in this way with the typhoid culture to a suspected germ it can be determined with a high degree of certainty whether or not that germ is a genuine typhoid bacillus. This is the method of differentiation and identification commonly employed at the present time.

Q. How does the longevity of the typhoid bacillus in the human body compare with that in soil or in water?

A. From the available data it appears that under certain conditions a typhoid bacillus may remain alive for weeks or even for months in the human body. There are cases on record where even years after an attack of typhoid fever the typhoid bacillus has been found in the bone marrow and other situations in the body of human beings. Outside of the human body on the other hand the life of the typhoid bacillus is comparatively brief. There is no evidence that it can remain alive in water for more than a few days. It may remain alive in accumulations of dejecta in out houses and privies for a much longer time and in the soil also it may retain its vitality for a consideable period.

9848 Q. Will you state the established instances where the typhoid bacillus has been detected in potable water?

Mr. Jeffries: I object to the question for the reason that typhoid bacilli have never been detected in potable water, using the term potable as applied to sanitary science.

Mr. Todd: I use it in the sense in which it was employed by Dr. Teichmann in giving his testimony.

A. Although the evidence which connects polluted water supplies with outbreaks of typhoid fever is entirely convincing both in character and mass, there have been relatively few instances in which bacteriologists have succeeded in isolating a specific typhoid bacillus from suspected waters.

In view of the insufficiency of the data relied on for identification most of the early statements concerning the finding of the typhoid organism must be regarded as of an exceedingly doubtful value. The criteria upon which up to a very few years ago such identification was based would by no means be accepted by bacteriologists of the present time. Especial uncertainty has again been recently introduced into the subject by the discovery of the group of dysentery and pseudo dysentery bacilli, of bacillus fecalis alcaligenes and of a host of related organisms.

9849 A survey of the literature shows that there are very few reported cases of the detection of the typhoid bacilli in water, which conform to present day requirements. Losener (Arbitin a. d. Kais. Gesundheits 1895, 11, p. 207) working in the Hygenie Institute in Berlin, isolated from the laboratory water supply an organism that agreed culturally with the typhoid bacillus in all respects and that also responded favorably to Pfeiffers' immunity test.

Remlinger and Schneider (Ann. de. l'Inst. Pasteur 1897, 11 p. 55) found in various natural waters organisms that possessed the biological qualities of a typhoid bacillus and that agglutinated with typhoid serum and also conformed to Pfeiffers's immunity test.

Some conservatism is shown, however, in accepting the work of these latter authors at its face value both because of their sweeping statements with regard to the "ubiquity of the typhoid bacillus" and because of certain other internal evidence in the paper referred to.

Hankin (Centrable f. Bakt. 1899, 26 p. 554) working in India found a typhoid like bacillus in samples of water derived
from various sources and substantiated his cultural ex-
9850 amination with the observation that agglutination oc-
curred with a 1 to 600 dilution of anti typhoid serum.

Kublar and Neufeld (Zeitschr f. Hyg. 1899, 31 p. 133) related a particularly interesting case of the finding of a typhoid bacillus in the water of a shallow well to which infection had been traced. In the course of the investigation it was noticed that no colon bacilli were present in the water, a fact that in the opinion of the authors pointed to infection with typhoid urine rather than with fecal discharges and that explains the relative ease with which the typhoid bacillus is isolated as well as the unusually long persistence of the organisms in the water. Both the agglutination test and Pfeiffers' test were employed to establish identification.

Genersich (Centralbl f. Bakt. 1900, 27 p. 241) isolated 11 cultures of typhoid like bacillus from the water of incriminated cisterns.| These organisms agglutinated in a dilution of 1 to 50 typhoid serum obtained from a human patient but the serum of animals inoculated with the water cultures failed to agglutinate a control typhoid culture except in a single instance.

Fischer and Flatau (Centralbl f. Bakt. 1901, 29 p. 329)
have reported an apparently unimpeachable case of the
9851 isolation of a bacillus from the water of a well at Rellin-
gen. Both the agglutination test and Pfeiffers' test were
applied with positive results.

There are, therefore, perhaps six cases where undoubted typhoid bacilli have been isolated from ordinary drinking water. If the evidence adduced by Remlinger and Schneider and by Genersich is not regarded as wholly convincing the number of such cases is reduced to four. On the other hand the finding of a paratyphoid bacillus in water by Simon and Negel (Centralbl f. Bakt. Orig. 1902 32 p. 480) may practically be put in the same category with the discoveries of genuine typhoid bacilli.

The meagreness of the findings despite the thousands of examinations that have been made by skilled bacteriologists in every part of the world is in my opinion explained chiefly by the relative short duration of the life of the typhoid bacillus in water. The period elapsing between the moment of infection and the initiation of bacterial investigation is usually at least two or three weeks, owing chiefly to the time occupied in incubation and in the insidious development and perhaps tardy
recognition of the disease. Some time is also consumed by
9852 the preliminaries necessary for the setting on foot of
competent investigation. It is apparently only under exceptional conditions, such for instance as obtained in the case reported by Kubler and Neufeld, that the life of the bacillus can extend throughout any considerable period. The history of most outbreaks of typhoid fever shows that the bacilli have disappeared from the water by the time search is inaugurated and

it is for this reason that a negative finding is the usual result of bacterial examination.

Q. Have you investigated the longevity of the typhoid bacillus in different kinds of water in laboratory experiments?

A. I have.

Q. Will you give the results of those experiments?

A. These experiments were made upon the life of the typhoid bacillus in sterilized waters, kept in glass bottles in the laboratory. They showed, among other things, that the age of the typhoid stock influences a good deal the life of the bacilli introduced into the water, a freshly isolated stock possessing distinctly greater vitality than one that had been under cultivation for some months. The typhoid bacillus when introduced with
proper precautions into sterilized Lake Michigan water
9853 does not multiply but may under certain conditions main-
tain its vitality for upwards of 93 days. The colon bacillus on the contrary under similar conditions undergoes rapid multiplication and may remain alive for upwards of 262 days. In redistilled water the typhoid bacillus perishes much more speedily than in the water of the Lake. It may be noted that all these experiments were made with sterilized water and in glass bottles.

Q. Does the typhoid bacillus multiply and increase in nature?

A. I know of no evidence that this occurs. On the contrary from an examination of literature the evidence appears to me overwhelming that typhoid bacilli once discharged from the human body undergo a constant diminution in number.

Q. Are the conditions of laboratory experiments more or less favorable to the longevity of the typhoid bacillus than the conditions that obtain in nature?

A. In my opinion they are decidedly more favorable.

Q. Will you please state your reasons for that opinion?

A. It has been shown by experiments made by Ficker
(Zeitschr F. Hyg. 1892, 29 p. 1) that water sterilized in
9854 glass bottles brings into solution substances which favor
continued vitality on the part of the various micro organisms. These experiments are well known and show how peculiarly favorable are the conditions in these glass bottle experiments for the long life of the microbes introduced.

Q. Will the germ of typhoid live as long in polluted water as in pure or sterilized water?

A. No sir, I think it will live longer in pure water than in polluted water and it is well known from the experiments of many observers that it lives longer in sterilized water than in unsterilized.

Q. How do you account for this?

A. I attribute the relatively speedy death of the typhoid bacillus in polluted waters as compared with pure and in unsterilized waters as compared with sterilized to the action of the various saprophytic microbes which inhabit these waters. Where the typhoid bacilli are removed from competition with these saprophytic forms as in the case where they are introduced into sterilized waters they live longer than under the conditions where they may be injuriously infected by the products
of other microbes. In the case of the polluted waters the
9855 greater concentration of organic matter may favor a
more intense action of the products of the saprophytic
microbe present in these waters. In other words these products in the polluted water are in more concentrated form than is the case in the pure water, and so bring about the death of the typhoid bacillus sooner. It is therefore to the action of the saprophytic microbes that I attribute the dying off of the typhoid bacillus in polluted waters and in unsterilized waters.

Q. From your knowledge of the character and quality of the waters of the Drainage Canal, the Desplaines River and the Illinois River what is your opinion as a bacteriologist as to the longevity of the typhoid bacillus in these waters?

A. From what I know of the chemical composition and bacterial content of the waters of the Illinois River at various points along its source it is my opinion that the life of the typhoid bacillus introduced into the Illinois River at the upper end of the Drainage Canal would not be more than three or four days.

Q. What reasons have you for the opinion that the life of a
typhoid bacillus in the waters of the Drainage Canal, the Des-
plaines and the Illinois Rivers is shorter as compared
9856 with the laboratory experiments?

A. In the water of the Desplaines and the Illinois Rivers the typhoid bacillus is subjected to the unrestricted action of the products of the various saprophytic microbes that inhabit these waters. The large amount of organic matter in the upper stretches of the river favors the concentration and the consequent intensity of action of these saprophytic products. As compared with the laboratory conditions again the typhoid bacillus can hardly be favored in these rivers by the presence of any such substances as go into solution from the glass bottles used in laboratory tests. These two reasons, therefore, the absence of the favoring laboratory conditions and the free and vigorous action of the products of growth of saprophytic microbes lead me to adopt the opinion that I have just expressed.

ADJOURNED UNTIL 10 O'CLOCK FEBRUARY 3, 1904.

9857 10:00 A. M., Wednesday, February 3, 1904. Continuation pursuant to adjournment. Present, the Commissioner and same Counsel representing the respective parties.

PROF. EDWIN O. JORDAN

resumed the stand for further direct examination by Mr. Todd and testified as follows:

Q. Are you acquainted with the Chicago River, the Drainage Canal, the Desplaines River, the Illinois River and the Mississippi River from Grafton to St. Louis, and the Missouri River as it empties into the Mississippi?

A. In a general way I am.

Q. What opportunities have you had for acquainting yourself with the Drainage Canal?

A. I have been several times by train along the course of the Drainage Canal from Chicago to Lockport. I have several times visited the Bear Trap Dam at Lockport, and I have been by water from near the mouth of the Chicago River to the Bear Trap Dam at Lockport along the full course of the drainage canal.

Q. What opportunities have you had for acquainting yourself with the water course from the Bear Trap dam to Grafton, including the Desplaines and Illinois Rivers.

9858 A. I have been to Joliet and inspected the conditions at that point on the Desplaines River. I have visited Morris during the progress of this investigation on a number of oc-

casions, and have spent some time on the Illinois River between Morris and Ottawa in a boat, carrying out special observations and making hourly examinations of the river water at these points. I have visited Ottawa and examined the conditions prevailing about and below this town. I have observed the point where the Fox River empties into the Illinois at Ottawa. I have been to La Salle and examined the conditions in the Illinois River and the Big Vermillion at this point and have also noted where the old Illinois and Michigan Canal finally empties into the Illinois River at La Salle. I have been to Peoria and have been out on the Illinois River in a boat, above and below this place. I have been to Pekin, to Havana, and to Beardstown. I have visited Grafton at the mouth of the river a good many times, and have spent several days there on various occasions, making examinations of the river water and the conditions prevailing at that point. I have personally made bacterial examinations of the water from the Illinois and the Mississippi
Rivers at Grafton, doing the plating on the spot. I have
9859 also traveled down the Illinois River from La Salle to
Grafton by day light in steamboat and have observed the physical and topographical conditions throughout this stretch of the river. I have been out on the Mississippi River at Grafton and at Alton and have examined the conditions surrounding the mouth of the Missouri River where it empties into the Mississippi below Alton. I have also passed in a steam boat by daylight from Grafton to St. Louis, viewing the conditions existing along the course of the Mississippi River between these points. I have several times been out to the water intake of the St. Louis water works at the Chain of Rocks, have collected samples there myself and am generally familiar with the conditions in this neighborhood.

Q. During what periods were these visits made, as you have indicated?

A. My first trip along the course of the Illinois River was made in March, 1899 and my latest visit in September, 1903. The other visits to the several collecting stations and trips on the river were made at intervals between these dates.

Q. Will you describe the physical conditions of the Illi-
9860 nois River?

MR. JEFFRIES: He is giving his own descriptions!

MR. TODD: His own descriptions of what he personally knows of the conditions.

Q. And its tributaries?

A. From the point where the drainage canal empties into the Desplaines River at Lockport, the fall is quite rapid to a point somewhere below Morris. The lower portion of the Illinois River, especially that part of the River from La Salle to the mouth of the Illinois at Grafton is very sluggish and consists of a series of pools in which the current is very slow and in which opportunities for sedimentation abound. In the lower reaches of the river the current is so slight as to be hardly noticeable. At intervals in the course of the river, dams are located; one at Marseilles, between Morris and Ottawa, one at Henry, between La Salle and Averyville, one at Copperas Creek, some 58 miles below Peoria and two others between this point and Grafton at La Grange and Kampsville. These dams accentuate the tendency of the river to form pools and back waters. At Joliet and above Peoria there are wide expansions of the river known respectively as Lake Joliet and Lake Peoria. In these expanded reaches the current is very slight and the
body of water as a whole is almost entirely quiescent. At
9861 many points along the course of the river, especially be-
low La Salle, the banks of the river are low and an increase in the height of water in the river causes an overflow of the surrounding country, flooding the meadows and low lands adjacent to the river bank. In the lower 225 miles of the Illinois River there is a fall of only about 30 feet and the extremely sluggish current thus produced affords nearly ideal conditions for sedimentation. During the flood stages the valley of the Illinois River becomes virtually a great lake into which flood waters from the upper portion of the valley and tributaries are precipitated, and from the lower end of which they pass out in diminished and equalized volume.

Q. What effect do the lakes along the Illinois River, between Chicago and Grafton, have as a factor for the elimination of the infection and pollution entering the Desplaines River through the drainage canal from the sewers of Chicago?

A. If it were true that any of the infecting and polluting matters from Chicago reached as far down even as Lake Peoria the conditions existing there and further down the Illinois

River would be such as to bring about a further dimin-
9862 ution in the amount of the substances. Under the circumstances of semi-stagnation already enumerated, the settling out of food particles, the entanglement of the bacteria in these, and possibly the slow sinking of the bacteria themselves would all have full effect and would work to diminish the number of suspended bacteria.

Q. From what other sources than that of the drainage canal does the Desplaines and Illinois River receive pollution?

A. The sewage of Joliet, a city with a population of some 29,000, empties into the Desplaines River, as does also the sewage from a number of the suburban towns near Chicago. The Kankakee River, which unites with the Desplaines to form the Illinois, above Morris, also receives sewage from Kankakee of a population of about 14,000, and other communities. On the Illinois River the sewage from Ottawa, a sewered town, with a population of about 11,000, and the sewage of La Salle and Peru, with a combined population of nearly 20,000, also empties into the Illinois River. The Fox River which enters the Illinois above Ottawa, receives the sewage from Aurora, with a population of some 25,000 and of Elgin with a population of about 23,000. The Big Vermillion River, entering the Illinois
9863 above La Salle, also receives drainage from Streator and Pontiac, with a combined population of about 19,000. A very large amount of pollution enters the Illinois River at Peoria, with a population of about 56,000. In addition to the sewage of the town, the drainage from the stockyards and the distilleries enters the river here. At Pekin a sewered town, with a population of about 9,000 considerable sewage and distillery refuse also enter the river. The sewers of Havana also discharge into the Illinois River. The Sangamon River, one of the chief tributaries of the Illinois, receives a considerable amount of sewage from Springfield, with a population of about 25,000, from Decatur, with a population of about 20,000 and Bloomington, with a population of about 24,000. Beardstown, with a population of about 5,000 is the last town upon the Illinois River contributing a very large amount of sewage, the other towns below Beardstown being relatively small communities. All along the course of the Desplaines and the Illinois Rivers and their tributaries, in addition to these urban com-

munities, there is a very considerable rural population often draining directly into the river or small tributary streams,
9864 and this constitutes a source of pollution and possibly infection, not to be ignored.

Q. Considering all sources of pollution and infection entering the Illinois River from its tributaries and towns lying along its shores, and the City of Chicago, as well as its rural population, what importance do you attach to the dams and lakes and physical conditions of the river as a factor in the purification of said stream, at all times and under all conditions that obtain in the Illinois River?

A. I regard the conditions of semi-stagnation prevailing in the Illinois River at most points along its course as an important factor in influencing the fate of polluting and infectious matters added to the water of this stream and to the various tributaries. The exceedingly low gradient in the river which has been already referred to and which is further accentuated by dams at various points, retards the progress of suspended matters down stream and affords highly favorable conditions for purification. This is most marked during period of low water but at high water the flooding of the low-lands and the meadows along the banks of the river also affords opportunity for sedimentation and the retarding influences are still
9865 active. It is my opinion that the conditions prevailing in the Illinois River during summer and winter, during low water and high water, are much more favorable to the self purification of the stream than conditions that exist in a stream flowing over a bed with a steep gradient where any infectious elements introduced might be hurried down without opportunities for sedimentation or for loss of vitality. The considerable time that must be consumed by a given mass of water flowing along the Illinois River affords opportunity for the death and destruction of such infectious and polluting matters as may be introduced into this river, either directly or from the tributaries.

Q. Will clear water afford greater or less opportunity for the sedimentation of bacteria than turbid water containing matter in suspension?

A. Supposing that the velocity of the current is slow enough to allow the settling out of the particles of matter that impart turbidity to the water then any bacteria that might be in suspension, in such a water, would be carried to the bottom more quickly in a turbid water than in a clear water under similar conditions of movement. This has been proven experimentally by suspending in water bacteria together with 9866 clay particles and other substances, and allowing settling to occur. It is found that when there is a considerable amount of suspended matter in the water, bacteria are more quickly dragged down than when the water is relatively clear.

Q. Is the degree of sedimentation in the Illinois River affected by diluting the sewage of Chicago with Lake Michigan water?

A. There is at times a considerable amount of suspended matter in the water of Lake Michigan, near the mouth of the Chicago River, but on the whole the water of Lake Michigan is not a turbid water. In that portion of the Illinois River, however, where most sedimentation obtains, the amount of suspended matter introduced into the water from the tributaries and entering the river directly, is, in my judgment, sufficient to affect the same degree of sedimentation that would occur if the present amount of dilution with Lake Michigan water at the extreme upper end of the river was absent.

Q. If all the sewage of Chicago is turned into the drainage canal, diluted by one million cubic feet of Lake Michigan water per minute passing over the Bear Trap Dam, would that amount of dilution with Lake Michigan water affect the 9867 sedimentation of bacteria in the Desplaines and Illinois River under the conditions that obtain in those rivers?

A. In my judgment such a dilution as that indicated would affect the degree of sedimentation in the Desplaines River and probably in the upper part of the Illinois near the union of the Desplaines and the Kankakee, but in the lower part of the Illinois River, especially in that stretch from La Salle to Grafton, where sedimentation is most active, it is my opinion that such dilution as that described would not materially affect the degree of sedimentation of bacteria.

Q. Why?

A. From what I know of the physical conditions of the Illinois River and of the character of the various tributary streams, it is my opinion that there would be sufficient suspended matter in the water to bring about a mechanical dragging down of bacteria, and, moreover, that such an increase in the body of water as might result from this dilution would result in the spreading out of water of the Illinois River over the low lands, thus affording peculiarly favorable conditions for the sedimentation of bacteria.

9868 Q. What significance does dilution have in considering the problem of the self purification of streams?

A. When polluting or infectious matters are added to a water it naturally follows that the greater the dilution of such matters the less dangerous is a given quantity of such water, such for instance as a quart or a liter. In this sense dilution with a purer water may be said to increase the purity of the stream. So far as the actual destruction of infectious elements is concerned, dilution to such an extent as usually occurs, probably has but little influence.

Q. Is the danger of infection really diminished by dilution?

A. It certainly is.

Q. In what way?

A. Suppose that infectious material was introduced into sewage to such an extent that each tumblerful of the sewage contained one typhoid bacillus. Suppose further that such sewage were diluted with nineteen times its bulk of pure and uninfected water, it would then be true that out of one hundred glasses of this mixture of sewage and pure water only five would contain typhoid bacilli instead of the whole one hundred as was originally the case. In other words the same effect is
obtained as if 95 per cent. of the typhoid bacilli per-
9869 ished. In this way dilution unquestionably diminishes
the danger from infection.

Q. What effect does the dilution of Chicago sewage with the pure water of Lake Michigan have upon the condition of the water in the Illinois River?

A. Considering the conditions at the mouth of the Illinois River above Grafton, I should say that such dilution has little if any effect upon the infectious quality of such water, since whether the sewage be diluted or not, death of any typhoid bacillus originally present therein would occur, in my opinion, long before the mouth of the Illinois River was reached.

Considering the character of the Desplaines River at Joliet, however, such dilution would diminish the danger to any person venturesome enough to partake of the fluid at this point, since the dilution would diminish the number of typhoid germs contained in a given quantity, say a tumblerful of the mixture.

Q. Is the addition of Lake Michigan water to the sewage of Chicago a detriment or benefit to the sanitary condition of the Illinois River, in its upper branches, considered from the standpoint of dilution alone?

9870 A. If by sanitary condition is meant the infectivity of a given measured quantity of the water, such dilution would improve the Illinois River water in its upper stretches. So far as the destruction of typhoid bacilli is concerned, it is my opinion that this dilution has little or no influence upon the longevity of this microbe. The actual number of typhoid bacilli passing a given point would not be materially influenced by dilution, but the proportional number in a given quantity of water would of course be lessened.

As regards the process of decomposition which goes on in such sewage and sewage polluted waters, the river water is rendered much less offensive by dilution with the purer water of Lake Michigan, as I have observed myself to be the case at Morris. An improvement in the quality of the river water is also evidenced by the fact that fish now come up the Illinois River as far as Morris, where prior to this dilution they had not been known for years.

Q. Professor, I will ask you this question which was asked of Professor Sedgewick, on page 3542 of the record: "Professor, assuming the fact that the waters of the Chicago Drainage Canal, taken from points in Lake Michigan at or near the mouth of the Chicago River, were to be conveyed from Lockport to Grafton on the Mississippi River, through a canal or closed conduit, so built as to maintain the same velocity of flow provided in the present canal, built as far as Lockport, and further assuming the contents of this canal or conduit received none of the Chicago sewage except such portion as now reaches Lake Michigan directly, and without entering the Chicago River, do you or do you not consider that the assumed conditions above mentioned would constitute a menace 9871 or danger to the inhabitants of the State of Missouri, and especially of the City of St. Louis, drinking the Mississippi River water in its raw condition, the waters of the drainage canal flowing to the extent of 300,000 cubic feet per minute, emptying into the Mississippi River."

A. Assumming the question as quoted to apply to the passage through a conduit of the water of Lake Michigan, under the conditions stated, from the Lake Front of Chicago to the Mississippi River at Grafton, I would say that I do not consider that it would be a menace or danger to the inhabitants of the State of Missouri and especially to the citizens of St.
9872 Louis drinking the Mississippi River water in its raw condition. I make this answer because in my opinion the typhoid bacillus would not survive exposure to the conditions in such a closed conduit any more than in my opinion it does survive exposure to the conditions existing in the Illinois River. And furthermore, assuming that no greater mixing of such water with the waters of the Mississippi River and Missouri River occurs than is the case at present it is my judgment that a very small portion of such water would reach the intake tower of the St. Louis waterworks, pass through the settling basins and be delivered to the inhabitants of the City of St. Louis.

Q. Would such a volume of Lake Michigan water emptied into the Mississippi River in the manner indicated in General Crow's question, co-mingling with the waters of the Mississippi, and thence with the waters of the Missouri, ever pollute and infect the said waters of the Mississippi and Missouri Rivers as the same should pass along the shore of the State of Missouri and the City of St. Louis, at the St. Louis intake?

A. On the contrary, assuming the conditions in the Missouri and Mississippi River to be as they are at present, it is my judgment that the water issuing from such a conduit,
9873 and experiencing the same degree of purification which now takes place in the Illinois River, would tend rather to improvement and purification of such water so far as it might mingle with it.

Q. How do the physical conditions of the Illinois River compare with the other rivers in the country for the purpose of purification?

A. As compared with rivers of high velocity the conditions for purification in the Illinois River, as already set forth, are especially favorable. The sluggish current which permits a sufficient lapse of time for the death of pathogenic bacteria and which also facilitates and furthers sedimentation constitutes an element wholly favorable to self purification.

As compared with the Mississippi River where the current is swifter and especially as compared with the Missouri River the opportunities for purification in the Illinois River are quite superior.

Any factors that tend to increase the opportunities for sedimentation and that tend to delay the progress of pathogenic microbes down stream further the process of purification. In
these respects the conditions in the Illinois River are
9874 greatly superior to the conditions in the Mississippi and
Missouri Rivers. As compared with some other streams in this country that have been studied with a view to the opportunities for self purification the Illinois River is well adapted for self purification.

I find in the report to the Filtration Commission of Pittsburg, Pennsylvania, published in January, 1899, in a Report upon the Sources of Typhoid fever in Pittsburg, by my friend Professor W. T. Sedgwick, who has testified in this case the following statement: I will quote what he says about the Allegheny River under the heading "The Allegheny River a rapid stream with little or no opportunity for self purification," page 18.

"Any one who will take the trouble to follow the Allegheny River from Oil City to Pittsburg merely as a passenger on the Allegheny Valley Railway, particularly if he is familiar with the streams in the less mountainous parts of the country can not fail to be impressed immediately with the fact that we have in the Allegheny River a peculiar and characteristic stream. Owing no doubt to the character of the rock through which it has cut its way, it exhibits a very regular deep line from Oil City to Pittsburg. There is no mill dam of any consequence between these two cities and the river is therefore narrow as is
not frequently the case with rivers in New England and
9875 elsewhere in which a series of mill ponds containing
slowly moving water, and in which the elements of sluggishness and quiesence are except in period of freshets a chief

characteristic, but rather, even at low water like a brawling brook, making its way rapidly over a stony bed in which are very few pools or other quiet places adapted to purification in which there is little or no evidence of effective sedimentation as is proved by the absence of mud banks, sand bars and the like—but exhibiting everywhere stones polished by the swiftly flowing stream and without effective lodging places for mud or bacteria. An estimate roughly made of the rate of flow shows to the traveller a probable velocity in most places of at least a foot per second and often much more than this even at low water. With high water the velocity must obviously be much more rapid. Clearly the two fundamental elements looking towards self purification in rivers are here wanting, namely time and quiescence. The velocity of the river and the character of its bed are such that foul water introduced for example at Oil City or nearer points may and indeed must arrive at Pittsburg within a very few hours. Fortunately however we do not have to rely on the rough observations of passing travellers but are in 9876 possession of authoritative calculations. According to results obtained from the United States Engineer's office at Pittsburg the average velocity of the Allegheny River even during low water is from one to two miles per hour. During high water it is from 7 to 8 miles per hour and on the average of about three and one-half miles. This means that infectious materials poured in at Oil City of nearer points may arrive at Brilliant within fifteen hours or even at low water must arrive within a few days.

It has just been shown that in the bed of the Allegheny River very little or no opportunity occurs for purification en route by the usual processes which are more or less effected in rivers."

I would say that I entirely agree with Professor Sedgewick that the Allegheny River as he describes it affords few opportunities for the process of self purification, and that I agree in his conclusions as to the rapid march of infectious material under such conditions. The conditions in the Illinois River, however, as hereinbefore set forth are very different from those prevailing in the Allegheny River. In the Illinois River as in other sluggish streams those elements that favor self purifica-

tion in rivers, namely time and quiescence, are present in
9877 force. There are few rivers in the United States with
which I am familiar where the factors making for self purification are so potent as they are in the case of the Illinois River. Both the Mississippi and Missouri Rivers are less favorable in this respect.

ADJOURNED until 2 P. M. same day, February 3, 1904.

9878 MET PURSUANT TO ADJOURNMENT AT 2. P. M, FEBRUARY 3, 1904. Present the Commissioner and same counsel.

PROF. E. O. JORDAN.

resumed the stand for further direct examination by Mr. Todd.

MR. TODD: Mr. Commissioner, have you got the last part of Professor Sedgwick's testimony given in connection with the Washington epidemic, as I would like to have the same for inspection.

THE COMMISSIONER: Professor Sedgwick has that part of the record with him in Boston, it being understood that he is to correct it and when he next returns to Chicago bring it to me to be signed, after we have gone over the corrections which he can make in conformity with the agreement heretofore entered into.

MR. TODD: I have a transcript of his evidence in my possession which has not been corrected or signed by him, and would like to predicate a question upon the testimony as I have it, as I will not have an opportunity to ask this witness this question after you have received the testimony from Professor Sedgwick with his corrections.

Q. Professor Sedgwick on page 369 of the transcript of his testimony, an uncorrected copy of which I have, stated: "The River Commissioners of Great Britain, in a report pub-
9879 lished by them in 1874, state there is no river in England
long enough to purify itself from any sewage admitted to it, even at its source;" that stands as one of the axioms of sanitary science today, that those River Commissioners in 1874 I think it was made that statement that there is no river in the United Kingdom I think they said, long enough to purify itself

of any sewage introduced into it, introduced at its source, and of course some of the rivers of the United Kingdom are very long." And again, on page 4398, this question was asked him: "Do you know how the distance from Cumberland to Washington by river compares with the length of the river Thames in the United Kingdom" answered "The Thames is 209 miles long and is, I believe, the longest river in the United Kingdom, and this epidemic seems to confirm in a very remarkable way that statement of the Rivers Pollution Commission of Great Britain to which I have referred in my previous testimony where they said that there was no river in the world that was long enough to purify itself of any sewage introduced into it, even at its source." I will ask you if you are familiar with the report of the River Pollution Commission of Great Britain for 1874?

MR. JEFFRIES: I object to the question for the reason
that it is not a proper way to impeach, contradict or de-
9880 stroy the credibility of the testimony of Professor Sedg-
wick, but that counsel may introduce a copy of said report in evidence for that purpose, there being no showing that copies of said report are not extant.

A. Yes sir, I have frequently consulted it in connection with my teaching and investigation work.

MR. JEFFRIES: I move to strike out all that part of the question which relates to other than the witnesses acquaintance with the report in question.

Q. Will you state what the River Pollution Commission Report for 1874 did state about river purification?

A. The statement is as follows:

"It will be safe to infer, however, from the above results that there is no river in the United Kingdom long enough to effect the destruction of sewage by oxidation."

Q. What is the difference between the expression "to effect the destruction of sewage by oxidation" and the expression "to purify itself of any sewage introduced into it at its source?"

MR. JEFFRIES: I move to strike out the last preceding answer because it is not the best of evidence, and for the further reason that the witness did not attempt or claim to give all that
was said by said Commission upon the subject of self puri-
9881 fication of water in the rivers of the United Kingdom.

MR. TODD: In reply to the objection will state that when Professor Sedgwick testified to it in regard to what the report stated, he did not produce the report but assumed to testify from memory and the reference to this report is made frequently in his testimony as an axiom of sanitary science.

MR. JEFFRIES: In answer will state that what he has said may be true but that it does not necessarily follow that this board in its report did not say both what is attributed to it by Professor Sedgwick in his testimony and also what is said by this witness because the two statements, that made by Professor Sedgwick and that made by this witness, are not in conflict with each other.

Q. Question read.

A. At the time this report was published in 1874, the knowledge of sanitarians regarding the quality of a water was based on chemical data, this being before the rise of the science of bacteriology. Practically nothing was known at that time regarding the elements in sewage that imparted to it its dangerous character. The fact had, however, been determined empirically that a certain relation existed between the oxidation of sewage and the loss of its dangerous qualities. 9882
It was not known however precisely what this relation was or upon what it depended. At the present time our conception of the purification of a sewage-polluted stream is based rather upon what information we are able to obtain regarding the disappearance and destruction of disease producing bacteria that may be introduced into it rather than upon oxidation processes. There is, therefore, a wide difference between stating that the purification of a stream is effected within a certain distance and that the destruction of sewage by oxidation is accomplished within a certain distance. It does not, by any means, follow that because complete destruction by oxidation of the organic matters contained in a sewage polluted water does not occur within a specified distance, that the real purification of the sewage, that is to say its freedom from dangerous bacteria may not be accomplished within that distance. It is certainly true that the process of nitrification or oxidation and the processes leading to the disappearance of dangerous or suspicious bacteria do not always run in a strictly parallel course either in sewage tanks or polluted rivers.

Q. Does the report of the Rivers Pollution Commission

of 1874 contain anywhere in it the statement that no river
9883 in the United Kingdom is long enough to purify itself of
any sewage introduced into it at its source?

MR. JEFFRIES: I object to the question for the reason that counsel is undertaking to lead the court to believe that the language used by Professor Sedgwick in his testimony is the exact language used by the Commissioners in their report, and I object to it for the further reason that counsel is undertaking to get the witness to state or to relate to the court things that are not contained in the report, and while it is true that witness has stated that certain statements were contained in the report purporting to set out the exact language by the Commissioners in their report, yet the introduction of such statements do not justify this witness in undertaking to tell this court all that the Commission failed to specify, determine or say, and in this connection I suggest that the report must speak for itself as to what it does not contain.

Q. Question read.

A. I have examined this report with some care and have failed to discover in it any statement couched in the language you have just used.

MR. JEFFRIES: I move to strike out the answer because
the question and answer imply and undertake to con-
9884 vey to the mind of the court the impression that Professor
Sedgwick used exactly the identical language contained
in the report.

Q. Is there in that report any language that carries the idea expressed in the sentence "there is no river in the United Kingdom long enough to purify itself from any sewage admitted to it, even at its source?"

MR. JEFFRIES: I object to the question for the reason it is for the court to determine from the report itself whether or not there is any such language used that would convey the impression stated in this question, and not for this witness to determine such fact, and that all of these questions are unfair and irrelevant and incompetent because the report itself is the best evidence.

MR. TODD: I will suggest on the ground of fairness that if counsel who introduced Professor Sedgwick was actuated by the same degree of fairnesss that counsel is in filing his objections he would have had Professor Sedgwick produce the report and there could have been no misunderstanding, as this report has been referred to by several witnesses on the part of the complainant in this case.

9885 MR. JEFFRIES: I will state that whatever counsel may say with reference to fairness of counsel upon either side in this case, that such statements do not justify this witness in undertaking to state to the court whether or not the report contains or promulgates any such propositions as contained in the language expressed in this question, and it is not for this witness to say but for the court to determine upon all the evidence and from the report itself if counsel desires to introduce the report.

Q. Question read.

A. As I have already stated I have made a somewhat careful examination of this report, and the statement that I have found in it that most nearly expresses the idea embodied in the citation from the record, is the statement that I have already quoted.

Q. From your knowledge of the physical conditions that obtain along the Illinois river as well as your analyses of the water, both chemical and bacterial, what effect, if any, does the sewage from Chicago, discharged into the drainage canal, have upon the waters of the Mississippi river as the same passes along the shore of the State of Missouri?

A. The large amount of harmless inorganic chlorine in the
water of the Illinois river at its mouth is derived chiefly
9886 from the sewage of Chicago and Peoria. So far as the
water of the Illinois mingles with that of the Mississippi
along the Missouri shore, so far is the chlorine content of the
water heightened. In respect to the other constituents of the Illinois river water, the sewage introduced at Chicago influences the total amount of nitrogen compounds in said water. This is especially true of the nitrates, which are usually high at Grafton. In respect to the bacterial content of the water, the mixing of the Illinois with the Mississippi does not in my opinion introduce into the mixture any significant number of bacteria derived from the sewers of Chicago. It is my opinion that practically all the bacteria introduced into the drainage canal from the Chicago sewers perish long before the mouth of the Illinois is reached.

I conclude that the sewage from Chicago, introduced into the drainage canal, has no injurous effect upon the waters of the Mississippi as the same passes along the shore of the State of Missouri.

Q. What is your opinion as to whether any pollution, dangerous to public health, entering the drainage canal from the sewers of Chicago, reaches as far down the Illinois river as the town of Grafton?

9887 A. None.

Q. What evidence have you that justifies the conclusion just expressed that no pollution dangerous to public health coming from the sewers of Chicago, reaches as far down the Illinois river as Grafton?

A. All the analytical data that have been introduced by me in evidence justify, in my opinion, the conclusion that I have expressed, the rate of oxidation of the organic matters in the sewage, the enormous death rate among the sewage bacteria in the extreme upper reaches of the Illinois, and especially the high mortality among the colon bacilli, all combined to furnish convincing evidence that pollution dangerous to public health, coming from the sewers of Chicago, does not reach as far down the Illinois river as Grafton.

Q. What is your opinion as to whether any infectious matter coming from the sewers of Chicago, by way of the drainage canal, in a dangerous state reaches as far down the Illinois river as the city of Grafton?

A. I am unable to differentiate clearly between infectious matter and pollution dangerous to public health in this connection, since polluting matters dangerous to the public health are, so far as I am aware, those able to communicate infec-
9888 tion. I, accordingly, would answer this question in the same way as I have answered the preceding, namely, that in my opinion no infectious matter coming from the sewers of Chicago by way of the drainage canal reaches as far down the Illinois river as the city of Grafton.

Q. Is there any evidence, bacterial or chemical, that you know of that would justify the conclusion that polluted and infected matter coming from the sewers of Chicago would reach as far down the Illinois river as the town of Grafton?

MR. JEFFRIES: I object to that as leading and suggestive.

A. I know of no evidence, bacterial or chemical, that would justify such a positive conclusion. On the contrary, as I have stated, the evidence of which I am cognizant points to precisely the opposite conclusion, namely, that such deleterious elements do not reach as far down the Illinois river as the town of Grafton.

MR. JEFFRIES: I move to strike out the answer because the witness has confined himself to the evidence introduced in this case, and to his personal knowledge of the conditions, 9889 and does not state the source of the evidence to which he refers in his answer.

Q. Would a condition of low water in the Missouri river at a time when there was high water in the Illinois river be in any way a factor in carrying infected and polluted matter from the sewers of Chicago to the City of St. Louis?

A. In my opinion it would not. In my judgment the Illinois river at its mouth does not contain infectious matter of a dangerous character, derived from the sewers of Chicago, and so could not be a factor in carrying infectious and polluting matters from the sewers of Chicago to the City of St. Louis.

Q. Professor Sedgwick, in answer to this question (on page 3545 of my transcript of the record), "Professor, will you state whether or not it is within the bounds of human possibility for any competent expert to say that in the period of low water on the Missouri river, such as is likely to occur at next Christmas a thaw on the Illinois river watershed might not endanger the lives of the people using the waters of the Mississippi below the mouth of the Illinois on the Missouri shore and at the City of St. Louis by sending to them in that water the suspended sewage of the sanitary district of Chicago?" answered, "I do not believe that it is, because in my opinion no competent 9890 expert whatever can or will say that any means exist at present by which such unpurified sewage can be warded off from the people on the Missouri shore and the citizens of St. Louis under these conditions." I will ask you to state what is your knowledge in regard to the assumption that low water might exist in the Missouri at a time of flood water in the Illinois, and also state whether you know of any means existing in the Illinois river at present that would permit unpurified sewage from the City of Chicago to become a danger and a menace to the public health of the citizens of Missouri and the citizens of St. Louis using the water of the Mississippi river for drinking and domestic purposes.

A. In reply to the first part of the question I will state that it is of course conceivable that low water may exist in the Missouri at the time of flood water in the Illinois. During the period, however, that I have had a knowledge of the conditions of the water stages in these rivers I have not known such a condition as that described in your question to exist. It seems to me rather unlikely that a period of flood water in the Illinois would coincide with a period of low water in the Missouri.

In reply to the second part of the question I will state
9891 that the natural factors of self-purification that are observed in the Illinois river at present and that in my opinion lead to the death and destruction of pathogenic germs introduced into this river from the sewage of Chicago are sufficient to prevent unpurified sewage from Chicago from becoming a danger and a menace to the public health of the citizens of Missouri and the citizens of St. Louis. I assume that by unpurified sewage is meant sewage containing its original dangerous qualities. It is my judgment that the dangerous elements present originally in Chicago sewage do not pass down the Illinois river far enough to affect the public health of the citizens of St. Louis.

Q. Professor, from your knowledge of all the conditions that obtain along the Illinois river as well as your knowledge of the conditions that obtain in Chicago and the drainage canal, also your knowledge of the water supply of St. Louis, such as is had at the intake tower at the Chain of Rocks—what effect does the sewage from Chicago have upon the water supply of the City of St. Louis or upon the water of the Mississippi river as it passes along the shores of the State of Missouri?

A. From my knowledge of all the conditions indicated in your question, it is my judgment that the sewage of Chi-
9892 cago has no injurious or deleterious effect upon the water supply of the City of St. Louis or upon the water of the Mississippi river as it passes along the shores of the State of Missouri.

Q. Professor, will you please state upon what facts you base your opinion that a typhoid bacillus will not live more than three or four days under conditions as they obtain in the drainage canal, the Desplaines river and the Illinois river?

A. I base my opinion chiefly upon an elaborate experiment that I have recently carried out upon the life of the typhoid bacillus under natural conditions in the water of the drainage canal at Robey street, and at Lockport.

Q. Was this experiment conducted by yourself alone?

A. No, sir; by arrangement with the Sanitary District of Chicago the experiment was conducted under the supervision of Professors Russell of the University of Wisconsin, Zeit of the Northwestern Medical School and myself. It was a co-operative experiment, special features of the work being assigned to each investigator.

Q. Professor, will you give the general plan of the experiment?

9893 A. The experiment was planned with a view to imitating as closely as possible the conditions that would environ a typhoid bacillus introduced into the drainage canal from the sewers of Chicago.

I have already indicated the serious and insurmountable objections to experiments upon the longevity of a typhoid bacillus in glass bottles under laboratory conditions. With a view to removing these objections a different receptacle was planned for imprisoning the typhoid bacillus in the drainage canal under normal conditions of life, temperature, etc. Five different bodies of water were selected for the experiment, namely, the water of Lake Michigan, the water of the Chicago river, the water of the drainage canal at its mouth at Robey street, the water of the drainage canal at Lockport and the water of the Illinois river at Averyville. Professor Zeit carried on the experiments in Lake Michigan water and the water of the Chicago river. Professor Russell carried on the experiments in the water of the Illinois river at Averyville; and under my directions experiments were carried on in the water of the drainage canal at Robey street and Lockport. To avoid the use 9894 of glass in these experiments parchment sacs were employed, one of which I have here. These parchment sacs contained about eight hundred cubic centimeters of water and were suspended in floats which I shall describe presently. These parchment sacs permit the passage of certain substances in solution but do not allow the bacteria to pass through their walls. The conditions under which the typhoid bacilli introduced into the sewage in these sacs are subjected are therefore almost precisely the conditions obtaining in nature, since the bacteria inside and outside of the sacs can not pass through the walls of the sacs, and yet the bacteria are subjected to the action of the toxic products or saprophytic microbes in the sewage. The parchment sac in brief acts as a prison for the bacteria. The bacteria themselves are otherwise under the same conditions as those obtaining in the drainage canal.

Q. Will you describe these parchment sacs in detail which you employed in this experiment?

A. These sacs were made of parchment tubing about two inches in diameter and were prepared from heavy parchment paper such as is used in chemical work for osmotic ex-
9895 periments. The sacs were fastened to a piece of glass
tubing some six inches in length and were firmly tied to this and sealed with a mixture of tallow and rosin. The sac was weighted so as to swing freely in the water when filled with sewage. These sacs were suspended in the water in a frame work covered with a wire screen which permitted free circulation of the water. This frame was made of fine strips of wood and was four feet long and three feet wide and three and one-half feet deep. The bottom, top and lower five-sixths of the sides and ends of this frame were covered with wire screen. The upper six inches of the sides and ends of the box and the sides and ends of the cover six inches deep were of one inch pine fencing. The top opened with a hinge and was fastened in place by a hasp and padlock. The box was balanced in such a way that it floated with the water level up to the height of the lower margin of the upper solid portion of the body. The part above the water was thus of boards and served to break the waves from passing vessels or wind. At Robey street the box
was set between the timbers of a large floating frame.
9896 The wire covering the box had two and one-half meshes
to the inch. At Lockport the box was fastened to the floating dock near the Bear Trap Dam. The wire covering the box is of a three-quarter inch mesh. At both of these places the

floats were situated in such a way as not to prevent free circulation of water through the large wire meshes. And from an observation of the conditions both at Robey street and Lockport I am confident that the water within the frames differed in no essential particular from the open waters of the drainage canal. Inside the box were several coarse strips about an inch above the water level in which slots were cut in intervals of about three inches to receive the glass ends of the tubes. Opposite each slot was a staple through which was passed a cord attached to the tube which was thus securely held in place. To guard further against the tipping of the tubes small slips were fastened across the slots to prevent effectually the accidental removing of the sacs. These boxes were fastened with a padlock and throughout the experiments the key to both boxes was in the possession of my chief assistant, Mr. Irons, no other person having access to those boxes. The lower end of the parchment sac was sealed. It was rolled up tightly and wrapped with thread. Both the upper and lower joints were saturated with a mixture of resin and tallow. The capacity of the sacs ranged from 700 to 800 cubic centimeters. The sacs were tested for cracks or punctures before leaving the laboratory and then again when they were filled in the field. To the lower end of each sac a small weight was attached which served to keep the sac in an upright condition in the water. A cord was also fastened to the lower end by means of which the sac was brought to the surface of the water and the contents agitated at the time of taking samples. The tubes were open to the air at the upper end, allowing a free interchange of the air and gases. Owing to the slight wavy motion that was usually present in the water there was a fairly constant though slight movement of the body of the sacs. After several days in the water the tubes became coated with a dark slimy shag material which on examination was found to consist of a species of bryozoan. It is found on all submerged plants and debris in the vicinity. It was most marked at Robey street, but was seen to a less degree at Lockport. 9897

9898 Q. The description which you have heretofore given applies to the part of the experiment which was conducted under your direct supervision, does it not Professor?

A. It does solely and entirely to that.

Q. The other branches of the experiment were conducted by Professor Zeit and Professor Russell?

A. Yes, sir, in general in the same way, but independently, under the control of those investigators.

Q. Did you three men consult together about the scope of the experiment and the methods to be pursued?

A. Yes, the general plan of the experiments and the details were discussed very fully by us before the work was undertaken. We also held conferences during the progress of the experiment.

Q. You have described now the equipment which you employed for the making of the experiment, have you?

A. Yes, the equipment used in making the experiment has been described.

Q. Will you describe now in detail the manner in which the experiment was made?

A. We considered it important to obtain cultures of typhoid bacilli which had not been weakened or attenuated by artificial cultivation. Since I had already shown in some experiments on the death of typhoid bacilli in water, as previously referred to in my testmony, that freshly isolated cultures lived longer in water than those that had been under cultivation in the laboratory for some time, and since certain individual differences sometimes existed between cultures obtained from different sources we considered it necessary to procure several cultures. Three cultures were employed in the experiments carried out in my laboratory. These were designated respectively as typhoid x 9899

typhoid y and
typhoid z.

Typhoid x was isolated on September 22, 1903, from the blood of a patient suffering from typhoid fever in the county hospital in Chicago. The symptoms of this case which I have here in detail are those of typical typhoid fever. The history of this case is as follows:

Mike L., age 26, laborer, Polish; date of admission 21st of September; date of death 26th of September.

History: Patient is Polish and speaks no English. 9900 No history can be obtained other than that he has been sick one week. By gestures it is learned that he has had pain in his head and neck and has some tenderness in abdomen, has a few drops of blood on his clothing which he says came from his nose.

EXAMINATION. General, young man about 25, medium stature, good physical development, well nourished, expression dull, skin hot and dry; breathing 30, quite shallow; pulse 100, regular; slightly dicrotic.

REGIONAL. Spleen, dullness extends to the ribs in mid sternal line; edge readily palpable beneath costal arch.

ABDOMEN. Rounded, well formed; two or three typical rose spots that disappear on pressure. No tenderness, no distention.

RESUME. September 22, 1903, 5 cubic centimeters of blood were drawn from medium bacillic vein of the right arm 9901 in a sterile manner. With this two flasks of plain bouillon and one of litmus milk each containing 100 cubic centimeters were inoculated. From these flasks the typhoid bacillus was isolated in pure culture.

TEMPERATURE. On the day of blood cultures ranged from 101 to 104, pulse 90, respiration 30.

Leucocyte count September 24, 1903, 8,000.

September 24, patient was transferred to the surgical side and was operated upon.

EXAMINATION. Patient received in condition of partial collapse; abdomen tymponitic and painful; respiration rapid and shallow; pulse rapid and weak; patient conscious but extremely weak.

TREATMENT: Laparotomy.

September 25, 1903, pulse 158 (by stethoscope). Pulse extremely weak, respiration rapid and shallow, abdomen very tymponitic and rather tense. Wound discharging profusely. Wound dressed, dressing saturated.

8:45 p. m. Lowest stitch removed and strip of iodoform gauze inserted. Gas escapes from wound.

September 26, 1903. Death 12:20 p. m.

9902 AUTOPSY. Perforative peritonitis.

Acute splenic tumor.

Ulcerative enteritis (typhoid ulcers).

I should state that these notes were made by Dr. E. C.

Rosenow, working under my direction. In this case was obtained a pure culture isolated from blood.

The history of isolation of typhoid Y which was found in the urine of a typhoid fever patient, was as follows:

Thomas W. S. admitted to the Cook County Hospital September 22, 1903 having been sick five days, age 22.

HISTORY onset. Began with headache, loss of appetite, pains in back and limbs and general feeling of malaise. No history of chill, vomiting, or sweats. Has slept poorly. Bowels had been very loose since taking salts on day of onset. No urinary symptoms. No epistaxis.

EXAMINATION. Reginal, abdomen, distension slightly above normal. Moderate tymponitis and considerable gurgling.

SPLEEN. Palpable. A few pin head sized red spots over abdomen, disappearing on pressure.

September 23, 1903. Temperature 102.8; pulse 84;
9903 respiration 20 at noon day of the disease.

September 25, 1903. Sputum examination negative as to tubercle bacilli.

Blood examination leucocytes 6,000. Widal not positive in one hour, 1 to 40 dilution.

September 28 (12th day). Widal positive.

September 30. General condition good. No complaint. Stomach was disturbed; some diarrhoea.

Examined the abdomen, distended; tymponitic.

Spleen palpable.

October 1, 1903. History contains the following note: Examination of feces and urine by Dr. Rosenow showed typhoid bacilli in both.

October 5, 1903. General condition good. Convalescence uninterrupted.

October 19. Patient is up and around. Clinical diagnosis, typhoid fever.

October 17, 1903. Specimen of urine collected and handed to Mr. Irons."

In regard to this case I want to say that in addition to using
in the experiment a culture of the typhoid bacillus isolated
9904 from the urine of this patient a sample of the urine itself
as collected under natural conditions was obtained from
this patient and added directly to the sewage in some of the sac

experiments, thus imitating as closely as possible the conditions under which typhoid bacilli pass directly from the body of a patient into the sewage in the ordinary urine dscharge.

'Typhoid Z. Mike, O. H. Of Irish descent; age 22 years; admitted to the Cook County Hospital August 28; died September 28th; no postmortem was held. The case was a perfectly typical one of typhoid fever. Typhoid bacilli were isolated from the patient's feces on September 28th.'' These three cultures, typhoid X, typhoid Y and typhoid Z were therefore all freshly isolated cultures obtained for the purposes of this experiment from typical cases of typhoid fever. One of these typhoid bacilli was obtained from the blood of a patient, one from the urine of a patient and one from the feces of a patient. The virulence of these organisms is shown by the fact that in two instances the outcome of the case was fatal.

9905 The aim of isolating these cultures in a fresh condition from the body of patients was to obtain the maximum degree of vitality and virulence, thus making the outcome of the experiment, whatever it might be, as valuable as possible from a scientific point of view and as conclusive as possible on the sanitary side.

Adjourned until 10:00 a. m., February 4, 1904.

9906 10:00 A. M., Thursday, February 4, 1904. Continuation pursuant to adjournment. Present, the Commissioner and same counsel representing the respective parties.

PROF. EDWIN O. JORDAN

resumed the stand for further direct examination by Mr. Todd, and testified as follows:

Q. Professor, will you describe the methods employed by you in developing the typhoid germs which you isolated from the blood, urine and feces of the three persons or patients concerning whom you testified at the close of yesterday's testimony?

A. In each case the material obtained from the patient's blood, urine and feces respectively was mingled with nutrient material in which bacteria are able to thrive. From this they were finally plated out in a solid gelatin or agar medium where each individual germ developed a colony about itself. Separate colonies were examined and the growth obtained in pure culture. The appropriate tests for the typhoid bacillus 9907 were then applied to the microbes so isolated. The growth was tested in gelatin, milk, nutrient broth, dextrose broth, the other usual bacteriological media. The morphology of the organism was then studied, its motility determined and finally the Widal test applied. By these methods it was definitely ascertained that the micro-organisms isolated from the bodies of these several patients were identical with the true typhoid bacillus, and these cultures after such complete identification were used in the experiments that have been referred to.

Q. Why did you select parchment sacs for use in this experiment?

A. For the reason that it was desired to imprison the typhoid bacilli where they might be under observation, and at the same time to imitate as closely as possible the natural conditions. Similar sacs made of celloidin have long been used in bacteriological work; they have been found particularly useful in performing experiments upon animals. Small celloidin sacs, filled with a fluid culture of bacteria, have been introduced into the bodies of animals under aspetic conditions. The advantage of the celloidin sacs used in this way is that it permits the 9908 solube products and toxins generated by the bacteria to pass through the wall of the sac while confining the bacteria themselves and not allowing them to spread through the body. This method has shed a good deal of light upon the action of the poisonous products of bacteria, as distinguished from the changes produced in the body by the presence of bacteria themselves. It was thought that by using similar sacs for these experiments upon the longevity of the typhoid bacillus in sewage, the advantages known to be derived from the use of such sacs in animal experiments would be obtained in the experiments upon sewage. In other words, under these conditions the soluble products of the typhoid bacilli would be free to diffuse into the surrounding liquid, and conversely, similar products of the sewage bacteria outside of the sac could diffuse into the sac. Any action that these products might have upon the typhoid bacilli could then be exerted under these conditions. The parchment sacs are of substantially the same character as celloidin

sacs and the parchment paper of which they are constructed is used commonly in dialysis in the chemical laboratory. The parchment sacs are somewhat stiffer and less fragile than the celloidin sacs and for this reason were used in the ex-
9909 periments in the canal. Parallel tests with large celloidin sacs of the same size and construction as these parchment sacs have given strictly analogous results.

To sum up, parchment sacs confining typhoid bacilli mingled directly with the contents of the drainage canal, represent natural conditions as closely, I believe, as it is possible to represent them.

Q. After the cultures were prepared in the manner you have indicated did any of your associates use these same cultures in similar experiments

A. Yes sir; these three cultures isolated and identified under my direction and designated respectively as typhoid X, typhoid Y and typhoid Z were sent to Professor Russell of the University of Wisconsin, and one of these cultures, typhoid Y, if I remember correctly, was sent to Professor Zeit.

Q. Who assisted you in these experiments?

A. Mr. E. E. Irons who was my principal assistant in a large part of the work that I carried out upon the Illinois River for some three years was assigned the important work of inoculating the sacs placed in the floats in the drainage canal,
9910 and also of obtaining samples from these sacs at times specified by me. After the floats were installed in the drainage canal at Robey Street and at Lockport I visited both these places with Mr. Irons and inspected the results of his work.

In the laboratory I was assisted by Doctors Norman McLeod Harris and Miss Mary C. Lincoln who worked with me and immediately under my supervision.

Q. How many sacs of the character that you have described were employed in making this experiment?

A. At Robey Street 16 and at Lockport 12. These were all inoculated sacs, that is sacs into which typhoid bacilli were introduced. In addition a number of sacs were introduced into the water at both Robey Street and Lockport which were filled with the sewage taken directly from these places and were used as control sacs.

Q. Will you explain what you mean by control sacs?

A. These sacs known as control sacs were not inoculated with typhoid bacilli but contained simply the raw sewage
9911 taken from the canal at the respective points. Samples of water taken from these control sacs were plated at frequent intervals and examined as to their bacteriological content, the aim being to discover what happened to the sewage bacteria, especially the colon bacilli and streptococci present in the sewage. It was thought that in this way some valuable information might be obtained as to the course of events in the sewage itself as it passes on down the drainage canal into the Desplaines and Illinois Rivers. Laboratory experiments with such sewage placed in glass bottles are open to the objection that they are not under natural conditions and so do not afford a true insight into the changes taking place in nature.

Our expectations regarding the value of these control sacs were fully justified by the outcome.

Q. Will you describe the method employed by you for the inoculation of these sacs with the typhoid bacillus?

A. The typhoid bacilli, X, Y and Z were grown upon the surface of nutrient agar, at the body temperature, for twenty-four hours. The surface growth was then scraped off and introduced into sterilized lake water or sterilized sewage,
9912 or in some cases into urine derived from typhoid fever patients. This suspension of typhoid bacilli, as it is technically called, was then introduced by Mr. Irons into the parchment sacs which had been filled with sewage from the drainage canal just prior to inoculation.

In order to determine precisely how many typhoid bacilli were introduced in each case, a measured quantity of the suspension already alluded to was diluted with a known quantity of sterilized water and plated in the usual way. By counting the number of colonies developing upon the plate the number of typhoid bacilli that were introduced into each parchment sac was determined with accuracy. By using a young—24 hours old—culture of typhoid bacilli isolated but a short time before, as already stated, every attempt was made to favor the introduction of the typhoid bacillus into the sewage in a condition of maximum vitality, and thus guard so far as possible the liability that the cultures employed were attenuated or weakened in any degree.

Q. After the sacs were inoculated what was the next
9913 step in the experiment?

A. Samples of water were collected from these sacs in sterilized glass bottles by Mr. Irons, according to my instructions. These samples were brought to the Bacteriological Laboratory of the University of Chicago as speedily as possible.

Q. What were your instructions for the collection of samples from these sacs?

A. Mr. Irons was directed to obtain the samples from certain sacs which I specified to him before leaving the laboratory. He was instructed to obtain the samples according to the most rigorous bacteriological methods and to use all aseptic precautions. Before collecting the samples Mr. Irons was told to agitate the contents of the sacs freely for some time so as to permit thorough mixing of the contents. The sacs were then tilted so that the fluid in them contained passed up in the glass tube and could be easily withdrawn by a sterilized pipette.

Mr. Irons was further told to observe very closely the condition of each sac at the time of collection and to notify me as to its precise condition. I may state here that during the course of the investigation it was found that after about fourteen days some of the sacs would break down owing to maceration and disintegration in the sewage. After the samples were
9914 collected under suitable bacteriological conditions, a procedure in which Mr. Iron's large experience in work of this sort was of great benefit, the samples of water were brought at once by him personally to the University Laboratory.

Q. After these samples were brought to the University Laboratory what was done with them?

A. Accurately measured quantities of the sewage into which typhoid bacilli had been introduced were mingled with special nutrient media of various kinds, and the mixture poured out into sterilized glass dishes. The amount of sewage used was such that a suitable separation of the colonies developing on these plates was arrived at. On the following day these colonies were examined by me and my assistants and any colonies that resembled typhoid colonies were taken from the plates and subjected to a searching examination.

Q. What methods were employed in the identification of the colonies?

A. We considered this from the outset as a most important part of the work. Until recently a considerable obstacle in the way of the isolation of typhoid bacilli in the presence of other organisms has been the difficulty of separating them
9915 readily from allied sewage bacteria. In planning the experiment the whole field of possible methods was canvassed and after many preliminary experiments certain media were found most suitable for the differentiation and identification of the typhoid bacilli.

I will describe simply those media that after many experiments we found to be most useful and to give highly satisfactory results.

9916 "Methods employed in making up the following media:

I. *Medium of Drigalski and Conradi.*

To two litres of sugar free broth were added

Peptone (Witte)	10 grams.
Nutrose	10 "
Sodium Chloride	10 "

and dissolved by the aid of heat. The mixture brought to the boil and sixty grams of agar-agar were added, and the mixture kept boiling until the agar was dissolved. Then the reaction of the mass was made weakly alkiline to litmus by the addition of sodium hydrate (4% sol).

This being done, a mixture of litmus solution (6%) and lactose (c.p.)

Litmus sol	260 cc.
Lactose	30 grams.

were added while both solutions were hot, and the whole boiled gently for five minutes. Then was added a solution of water-free sodium carbonate (10%) in the proportion of 4 cc followed by 20 cc of fresh solution of crystal violet (Grubler's)—o.1 gram in 100 cc water—and the whole mass filtered through cotton, tubed, and sterilized in the Arnold sterilizer for 20
9917 minutes on three successive days.

Ref.: Zeit. f. Hyg., 1902, Heft ii, p. 283.

II. *Medium of Drigalski and Conradi (modified).*

Modification was brought about by leaving out such constituents as nutrose, sodium chloride and solution of water-free sodium carbonate, and by filtering the mixture before adding the litmus lactose solution, a much clearer medium was obtained which scarcely contained any flocculent precipitate after being sterilized in the Arnold sterilizer thrice.

III. *Medium of McConkey, as modified by Grunbaum.*

Twenty grams each of agar-agar and peptone were dissolved in one litre of boiling water, and the whole made alkaline by adding 4 cc of a normal solution of sodium hydrate after having first brought the reaction to the neutral point of litmus.

Then was added while hot

Sodium taurocholate	5 grams
Lactose	10 "
Neutral Red (5% watery solution)	10 cc

9918 When the solution was complete the mass was filtered through cotton, tubed, and sterilized in the Arnold sterilizer once for twenty-five or thirty minutes.

Ref.: Brit. Med. Jour., 1902, Pt. 1, p. 1473

IV. *MacConkey's medium (Second modification)*

The medium having very little restraining power, crystal violet solution (1 gram to 100 cc water) was added in the proportion of 83 cc per litre of medium, and the technique was altered in the following ways:—After the agar and peptone were dissolved, the medium was made 1.8 acid in reaction to phenolphthalein by adding sodium hydrate solution, and the mass was antoclaved for five minutes at 120°C., cooled, cleared with white of egg, and filtered through cotton. This prevented a flocculent precipitate which formerly caused trouble in the original method.

Finally, the other ingredients were added, and also crystal violet solution as mentioned above, and the medium was tubed and sterilized once in the Arnold sterilizer for thirty minutes.

9919

V. *The plating medium of Hiss.*

Agar	15	gms.
Gelatine	15	"
Ext. of meat (Liebig)	5	"
Sodium chloride	5	"
Dextrose	10	"
Water (distilled)	1000	cc

The water being brought to the boiling point, the remaining ingredients were dissolved, reaction left unadjusted, and, after reducing the temperature to 60° C., the mass was cleared with white of egg, filtered, tubed, and sterilized for thirty minutes in the Arnold sterilizer on three successive days.

Ref.: Jour. Med. Research, 1902, v. VIII, No. 1, p. 148 (n. s. v. III, No. 1)

VI. Elsner's Medium.

Five hundred grams of potato, cut small, were put in a flask with 1000 cc. of water, and heated in an Arnold sterilizer for one hour and a half. Then the water was drained off and preserved, the potato mashed and strained, and finally 9920 cast out.

The water and strainings were mixed and brought up to 1000 cc by addition of water. To this fifteen grams of gelatine were added and the mixture boiled for ten minutes gently.

The reaction was made 2.4 acid to phenolphthalein. The mass was cooled at 60° C, cleared with white of egg, and filtered; then potassium iodide was added in the proportion of one per cent. and the medium was tubed and sterilized in the Arnold sterilizer for thirty minutes for three successive days.

Ref.: Zeit of Hyg. 1895, XXI.

HORROCKS GLUCOSE LITMUS AGAR.

Agar-agar	15	grams.
Peptone	10	"
Glucose	20	"
Water (distilled)	1000	cc.

Ingredients combined in the usual manner. Then sufficient aqueous solution of litmus added to give the medium a light blue color. For use the medium is melted, cooled at 42°
9921 C. and then deci-normal sodium hydrate added, so that each 10cc of the medium has an alkalinity equal to 1.8 cc decinormal alkali.

Ref.: An Introduction to the Bacteriological Examination of Water, by W. H. Horrocks, Lond., 1901.

9922 These methods, after careful experimentation and testing with the cultures employed gave satisfactory results and permitted identification of typhoid colonies with readiness.

I have some of the plates prepared by these methods from the infected sacs. I have in my hand a plate prepared in MacConkey's medium, as just described, showing the results obtained by plating sewage, into which typhoid bacillus from one of the X. Y. Z. cultures used in these experiments had been introduced. These plates have all been sterilized with formalin and are sealed with parafine.

The thin light blue colonies in this medium shown by holding the plate up to the light are colonies of typhoid bacilli, the small red colonies being colon bacilli. This medium greatly facilitates the differentiation of the typhoid bacillus, and also suppresses many sewage bacteria not belonging to the colon typhoid group, thus diminishing very greatly the total number of colonies appearing on the plate and rendering the separation of the typhoid colonies a much more simple process. When the plate is freshly prepared the color differentiation is even
9923 sharper than shown in this preserved specimen.

Mr. Todd: I offer this plate in evidence and ask to have it marked as Professor Jordan's Exhibit A.

Which said plate is marked by the Commissioner "Jordan's Exhibit A, Frank S. Bright, Commissioner."

9924 Professor Jordan: I have here also a plate prepared in a similar way, showing the mixture of typhoid bacilli from one of the X. Y. Z. cultures with sewage, this plate being made from the Drigalski Conradi medium, the blue colonies on this plate representing typhoid bacilli.

Mr. Todd: I offer this plate in evidence and ask to have it marked Jordan's Exhibit B.

Which said plate is marked by the Commissioner "Jordan's Exhibit B, Frank S. Bright, Commissioner."

9925 A. I have here a plate showing the same mixing of typhoid bacilli with sewage, this time plated in Hiss's medium. The very thin, delicate watery colonies on the surface of this medium represent typhoid colonies. I have encircled one of these with ink. The hardening of this medium for the purpose of preservation destroys something of the sharpness of differentiation.

Mr. Todd: I offer that plate in evidence and ask to have it marked Jordan's Exhibit C.

Which said plate is here marked by the Commissioner "Jordan's Exhibit C, Frank S. Bright, Commissioner."

9926 A. In the use of these media it was found that after a few days experience it was a relatively simple matter to pick off typhoid colonies from these plates. Mixtures of typhoid bacilli with sewage in the laboratory, showed, as has been stated, a great suppression of the ordinary sewage forms, and a rather sharp distinction between the typhoid bacillus and its near ally the colon bacillus which is always present in sewage in large numbers.

In such mixtures of typhoid bacilli with fresh raw sewage the great majority of colonies that were picked off as resembling typhoid colonies on these plates proved, on thorough examination, to be genuine typhoid bacilli, responding in all their characteristics to the strain of typhoid bacillus originally introduced. In most cases over 90 per cent. of the sewage bacteria were suppressed in these media and from those remaining typhoid colonies could be easily distinguished.

Q. Which one of these methods proved to be most satisfactory?

A. Four of these methods, namely the Drigalski and Conradi, the Horrocks, the Hiss and the MacConkey gave results which were in close harmony.

Towards the latter part of the work we became more expert in identifying the colonies appearing on Hiss medium 9927 than on the others, and some other advantages in the use of this medium also presented themselves, but throughout the investigation the four media were used side by side in practically all cases. Elsner's medium to which we gave a careful examination, did not prove so satisfactory as the others, and was not much used.

Q. Will you describe your method of identification of the typhoid bacillus in this experiment?

A. Typhoid-like colonies appearing on these several media were picked off from each plate. In all cases where it was practicable all of the typhoid like colonies on a plate were transferred to tubes and subjected to further examination, and on several occasions all the surface colonies of every kind appearing on the plate were picked off and transferred to tubes for study. These suspicious colonies were first inoculated into tubes of nutrient agar to which one per cent of sugar (dextrose) had been added.

All those in which gas productions occurred were discarded,
since the typhoid bacillus does not produce gas in this
9928 medium. From those tubes showing no gas production
a second transfer was made to tubes of sterilized milk to
which litmus had been added. The growth of the typhoid bacillus in such litmus milk is highly characteristic, and those tubes that did not show the initial slight acidity in litmus milk produced by the typhoid bacillus were discarded as being not true typhoid organisms.

All organisms passing these tests were then studied as to growth in dextrose broth, in gelatin and in respect to their various morphological characteristics.

Finally those organisms that ran the gauntlet of all these tests were subjected to the Widal test, and a positive reaction in this test established the final identification of the typhoid bacillus.

Q. Will you describe the method employed by you in tabulating the results of this experiment?

A. Particular attention has been paid to recording all the data obtainable in the case of these experiments. The number of ordinary sewage bacteria in the waters of the drainage canal at the respective stations has been determined by the usual colony count method. The number of colon bacilli present in such
waters has been determined and also the number of
9929 streptococcus forms present in these waters. On each oc-
casion a record has been kept of the number of typhoid
bacilli introduced into each sac together with the amount of

sewage contained in the sac so that information was had regarding the number of bacilli in each cubic centimeter of water in the inoculated sac.

The date on which the sample was collected is recorded; each sac was given a number that it retained throughout the experiment. The amount of sewage plated in each case is recorded in the tables. The medium from which the plates were made is recorded in each case and after the first few days the total number of colonies appearing on each plate is recorded. The total number of colonies picked off each plate, and whether these colonies were suspicious typhoid colonies or not, were all questions concerning which we have exact data.

The colony picked off from a plate for further study was given a serial number which allowed its complete identification at any time. Any culture that turned out to be from a genuine typhoid colony could be traced by this method to the exact plate and dilution from which it was obtained.

Thus, to take one instance, at random from the tables
9930 one cubic centimeter of sewage to which typhoid bacilli
had been added, was collected on seven days after the inoculation had been made. This was in Drigalski medium and 120 colonies in all developed on this medium. 25 colonies of these were picked off for further study, none of which proved to be typhoid.

Throughout the conduct of each experiment a record was kept of the temperature of the air and of the temperature of the water in the drainage canal at the point where the float was anchored.

Q. How were the results preserved, the results of this experiment preserved?

A. Typewritten record sheets were prepared, upon which the history of every sample taken, of every plate made, and of every colony studied, was accurately preserved. So that in every case we are able to establish precisely the grounds upon which the colony was discarded or upon which it was determined to be a genuine typhoid bacillus.

Q. Have you prepared tables showing the results obtained from this experiment?

A. I have.

Q. In what manner are those tables prepared?

A. They are typewritten copies, numbered and properly labeled, according to the point at which the experiment was carried out, and the number of the sac used in the experiment. 9931

Q. How many tables have you prepared for the experiment performed at Lockport?

A. I have six such tables.

Q. Will you produce and read table I?

A. Yes sir. It is as follows:

9932

TABLE I*

Drainage Canal at Lockport.

Initial colony count sewage bacteria	……	110000
" colon bacilli	……………………	4000—6000

*During the conduct of this experiment, Oct. 5-14 the temperature of the air ranged from 14° C to 19° C and of the water from 14.5° C to 17° C.

9933 Q. Will you explain table I?

A. Table I is the record of an experiment carried out in the drainage canal at Lockport, by the methods hereinbefore indicated, between October 5th and 14th, 1903. The temperature of the air during this period ranged from 14 degrees Centigrade to 19 degrees Centigrade that of the water from 14.5 C. to 17 degrees C. The sewage bacteria in the water of the canal at the time of inoculation was 110,000 per cc. The number of colon bacilli was 4,000 to 6,000 per cc. and the number of streptococcus 1,000 per cc. Bacillus typhosus, strain x, was added to this sewage in such numbers that each sac contained approximately 12,000 bacilli per cc. On the first day 60 colonies were taken from the plates. None of these proved to be typhoid colonies. On the second day 70 colonies were taken from the plates, none of which proved to be typhoid colonies. At three days 19 colonies were taken from the plates, none of which proved to be typhoid colonies. At five days 24 colonies were taken from the plates, none of which proved to be typhoid colonies. At seven days 45 colonies were taken from the
9934 plates, none of which proved to be typhoid colonies. At
nine days 45 colonies were taken from the plates, none of which proved to be typhoid colonies.

Two different sacs, B_1 and B_2 were used in this experiment.

9935 Q. Will you produce and read table II

A. It is as follows:

9936

TABLE II.*

Drainage Canal at Lockport.

9937 Q. Will you state what table II shows

A. Table II contains a record of experiments carried on in the drainage canal at Lockport on the same days and under the same conditions as the experiment described in table 1, namely, between October 5th and October 14, 1903. The initial number of sewage bacteria, the colon bacilli, and the streptococci were, of course, the same as that described in the preceding table.

A smaller number of typhoid bacilli, strain X, was added to this sewage in each sac. Each sac in this experiment contained approximately 600 typhoid bacilli to 1 cc.

Twenty colonies were taken from plates after one day.

30 after 2 days,
50 after 3 days,
24 after 5 days,
12 after 7 days,
10 after 9 days.

None of these proved to be typhoid bacilli.

Q. Will you produce and read table III?

A. It is as follows:

9938

TABLE III.*

Drainage Canal at Lockport.

Initial colony count sewage bacteria.. 110,000
" colon bacilli 4000-6000
" streptococci 1000

B. typhosus, strain (y), was added to this sewage in such numbers that each sac contained approximately 180 typhoid bacilli per cc. The bacilli were added in 5 cc of urine from a typhoid patient.

Time after inoculation	Sac No.	Amount plated in cc.	Medium	Colonies on plate	Colonies fished	Typhoid colonies found.

---

*During the conduct of this experiment, Oct. 5-14, the temperature of the air ranged from 14° C to 19° C and of the water from 14.5° C to 17° C.

9939 Q. Will you state what table 3 shows?

A. Table III contains a record of an experiment carried out in the drainage canal at Lockport between the same days as those reported in tables I and II, the character of the sewage being the same. In this experiment another strain of the typhoid bacillus, that previously designated as strain Y, was added to the sewage in such numbers that each sac contained approximately 180 typhoid bacilli per cc.

The bacilli were added in this case in 5 cc. of urine obtained from a typhoid fever patient.

13 colonies were picked off after 1 day,
20 colonies were picked off after 3 days,
12 colonies were picked off after 5 days,

20 colonies were picked off after 7 days.

And no typhoid colonies were found among this number.

Q. Will you produce and read table IV?

A. Table IV is as follows:

9940

TABLE IV*

Drainage Canal at Lockport.

Initial colony count sewage bacteria....	
" colon bacilli	1000
" streptococci	2000

B. typhosus, strain (z), was added to this sewage in such numbers that each sac contained approximately 30000 typhoid bacilli per cc.

*During the conduct of this experiment, Oct. 14-27, the temperature of the air ranged from 10°C to 17.5°C, and of the water from 10°C to 14.5°C.

9941 Q. Will you state what table IV shows?

A. Table IV contains the record of an experiment carried out in the drainage canal at Lockport. The initial number of sewage bacteria was in this case not obtained. The initial number of colon bacilli was 1,000 per cc. and the initial number of streptococcus 2,000 per cc.

During the conduct of this experiment between October the 14th and the 27th the temperature of the air ranged from 10 degrees to 17.5 degrees C. and that of the water from 10 degrees C. to 14.5 degrees C.

The bacillus typhosus, the strain previously designated as strain Z, was added to this sewage in such numbers that each sac contained approximately 30,000 typhoid bacilli per cc. After three days 40 colonies were picked off, none of which proved to be typhoid colonies.

After 5 days 24 colonies were picked off, none of which proved to be typhoid colonies.

After 6 days 17 colonies were picked off, none of which proved to be typhoid colonies.

After 8 days 24 colonies were picked off, none of which proved to be typhoid colonies.

After 10 days 26 colonies were picked off, none of which
9942 proved to be typhoid colonies.

Q. Will you produce and read table V?

A. It is as follows:

9943

TABLE V.[*]

Drainage Canal at Lockport.

Initial colony count sewage bacteria....
" colon bacilli 1000
" streptococci 2000

B. typhosus, strain (z), was added to this sewage in such numbers that each sac contained approximately 1500 typhoid bacilli per cc.

---

[*] During the conduct of this experiment, Oct. 14-27, the temperature of the air ranged from 10°C to 17.5°C, and of the water from 10°C to 14.5°C.

9944 Q. Will you state what table V shows?

A. Table V contains the record of a similar experiment carried out between the same dates as in the preceding case, namely, between October 14th and 27th, 1903, in the same body of water, differing from the experiment reported in table IV, only in the fact that each sac contained approximately 5500 typhoid bacilli per cc. instead of 30,000; 10 colonies were examined after 3 days, 8 after 5 days, none of which proved to be typhoid colonies.

These early experiments gave negative results throughout largely because of the number of typhoid bacilli added in these cases; but especially because in these early experiments the time allowed to elapse after inoculation before a very large number of colonies were examined was in most cases too great, as is shown by the later experiments in which a shorter interval was allowed to elapse between inoculation and examination of the material in these sacs. The experiment, for example, recorded in table IV where no examinations were made of the water of the sac until after 3 days had elapsed is a case in point.

The outcome of these early experiments convinced us that if typhoid bacilli were to be found at all in the waters of 9945 the drainage canal under these conditions it must be by examinations made within a short time after the infection of sacs had been effected.

Q. Will you produce and read table number VI?

A. It is as follows:

9946

TABLE VI.*

Drainage Canal at Lockport.

9947 Q. Will you state what table number VI shows?

A. Table number VI contains the record of an experiment carried out in the drainage canal at Lockport between October 17 and 27, 1903. The temperature of the air during this period was from 10 degrees C. to 17.5 degrees C. and that of the water from 10 degrees C. to 14.5 degrees C.

Initial colony count of the sewage bacteria was in this case not obtained.

The initial number of colon bacilli was 1,000 per cc.

The initial number of streptococcus was 2,000 per cc.

The bacillus typhosus, the strain previously designated as strain Y was added to this sewage in such numbers that each sac contained approximately 360,000 typhoid bacilli per cc.

In this case a particular test was made of the validity of the methods employed in isolation and identification.

10 minutes after the typhoid bacilli had been introduced varying amounts of the mixture of the sewage and typhoid bacilli were plated in three different media. In one of these cases .001 of a cc. was plated and there were 45 colonies
9948 in all on the plate. 14 of these colonies were picked out as looking suspiciously like typhoid colonies and on applying appropriate tests, as already described, 13 of these proved to be genuine typhoid bacilli. From this same sample of water .001 of a cc. of water was plated and 160 colonies in all developed on the plate. 18 of these were picked off as looking like typhoid colonies and 17 of them proved to be genuine typhoid bacilli. Of this same sample .001 of a CC. was plated in Hiss' medium, 230 colonies developed on the plate, 36 of these were picked off as resembling typhoid colonies and 33 of these proved to be genuine typhoid colonies.

The fact that on these three different media 63 out of 68 colonies that appeared to be like typhoid colonies turned out to be genuine typhoid organisms, demonstrates the great aid that these special media were in differentiating the typhoid bacillus in the presence of a multitude of sewage forms.

Continuing the record of this same experiment, after 3 days 65 colonies were taken off from 6 plates, a smaller quantity of water being used, instead of .001 of a cc. .01 of a cc. in one case and instead of .001 of a cc. .1 of a cc. Out of 65 colonies examined none proved to be typhoid.

9949 After three days out of 63 colonies examined, 2 out of 6 plates being from 1 cc. of the sewage, none proved to be typhoid.

After 5 days out of 46 colonies examined none proved to be typhoid.

After 7 days out of 42 colonies examined none proved to be typhoid.

After 10 days out of 85 colonies examined, none proved to be typhoid.

I consider this as one of the most remarkable of all experiments that were made. On the 10th day after inoculation 1 cc. of the contents of the sac was plated in Hiss medium and 85 colonies in all developed on this medium, which is not only very favorable to the growth of the typhoid bacillus but to all other sewage forms, its inhibitive effect being less than that of other media. Eighty-five colonies in all developed in 1 cc. of this sewage, and the whole number of 85 colonies was picked off the plate and examined and not one of these proved to be typhoid although 10 days previously when the sac was inoculated, each cc. in the sac contained 360,000 typhoid bacilli.

9950 This experiment plainly shows an enormous mortality among typhoid bacilli under these natural conditions in the water of the drainage canal. Examination of one whole cc. of the water after 10 days shows that of the 360,000 that it originally contained not one was left alive.

ADJOURNED UNTIL 2 P. M. SAME DAY.

9951 MET PURSUANT TO ADJOURNMENT AT 2 P. M., FEBRUARY 4, 1904.

Present the Commissioner and same counsel.

PROF. EDWIN O. JORDAN

resumed the stand for further direct examination by Mr. Todd.

Q. Do these six tables complete the work so far as typhoid determinations are concerned at Lockport during this experiment?

A. Yes sir, these six tables contain records of the inoculated sacs.

Q. Have you any tables from the Robey Street part of the experiment?

A. Yes sir, tables VII to XV, inclusive, deal with the experiments conducted in the drainage canal at Robey Street.

Q. Will you produce and read table VII?

A. It is as follows:

9952 TABLE VII*

Drainage Canal at Robey Street.

Initial colony count sewage bacteria....390000
" colon bacilli 4000–6000
" streptococci 2000

B. typhosus, strain (x), was added to this sewage in such numbers that each sac contained approximately 11500 typhoid bacilli per cc.

Time after inoculation	Sac No.	Amount plated in cc.	Medium	Colonies on plate	Colonies fished	Typhoid colonies found.

*During the conduct of this experiment, Oct. 9.-23, the temperature of the air ranged from 13°C to 18°C, and of the water from 12.5°C to 14°C.

9953 Q. Will you explain table VII?

A. Table VII contains the record of an experiment carried out in the drainage canal at Robey Street between October 9th and 23rd, 1903. During this period the temperature of the air ranged from 13 degrees C. to 18 degrees C. and that of the water from 12.5 C. to 14 degrees C. The number of bacteria present in the drainage canal at the time of inoculation was

390,000 per cc. The number of colon bacteria from 4,000 to 6,000; the number of strepticocci 2,000. Bacillus typhosus, the strain previously designated as X, was added to this sewage in such numbers that the sac contained approximately 11,500 typhoid bacilli per cc.

This was one of the early experiments and the first examination of the water was made four days after inoculation at which time 25 colonies were picked off. None of these proved to be typhoid. After 6 days 20 colonies were picked off, none of which were typhoid. After 7 days 15 colonies were taken off, none of which were typhoid. After 11 days 19 colonies were picked off, none of which were typhoid. After 12 days 41 colonies were picked off, none of which were typhoid. After 14 days 27 colonies were picked off, none of which were
9954 typhoid.

Q. Will you produce and read table VIII?

A. It is as follows:

9955 TABLE VIII*

Drainage Canal at Robey St.

Initial colony count sewage bacteria.....390000
" colon bacilli 4000–6000
" streptococci 2000

B. typhosus, strain (X), was added to this sewage in such numbers that each sac contained approximately 670 typhoid bacilli per cc.

Time after inoculation	Sac No.	Amount plated in cc.	Medium	Colonies on plate	Colonies fished	Typhoid colonies found.

*During the conduct of this experiment, Oct. 9.-23, the temperature of the air ranged from 13°C to 18°C, and of the water from 12.5°C to 14°C.

9956 Q. Will you explain table VIII?

A. Table VIII contains a record of an experiment carried out in the drainage canal at Robey Street between October 9 and 23, 1903. During this period the temperature of the air ranged from 13 to 18 degrees C. and that of the water from 12.5 to 14 degrees C. The number of sewage bacteria colon bacilli and streptococcus was the same as that indicated in table VII. Bacillus typhosus, a strain previously described as X, was added to the sewage in such numbers that the sac contained approximately 670 typhoid bacilli per cc. 2 days after inoculation 35 colonies were picked off, none of which proved to be typhoid. After 4 days 15 colonies were picked off, none of which proved to be typhoid.

After 7 days 23 colonies were picked off none of which proved to be typhoid.

Q. Will you produce and read table IX?

A. It is as follows:

9957

TABLE IX*

Drainage Canal at Robey St.

Initial colony count sewage bacteria.....390000
" colon bacilli .... 4000—6000
" streptococci 2000

B. typhosus, strain (3), was added to this sewage in such numbers that each sac contained approximately 18000 typhoid bacilli per cc.

Time after inoculation	Sac No.	Amount plated in cc.	Medium	Colonies on plate	Colonies fished	Typhoid colonies found.

9958 Q. Will you explain table IX?

A. Table IX contains the record of an experiment conducted in the water of the drainage canal at Robey Street, between October 9 and 23, 1903, the temperature of the air and water and the number of sewage bacteria per cc. and the number of colon bacilli and streptococcus being the same as indicated in tables VII and VIII. Bacillus typhosus, the strain previously designated as Z, was added to this sewage in such numbers that each sac contained approximately 18,000 typhoid bacilli per cc.

4 days after inoculation 50 colonies were picked off, none of which proved to be typhoid.

6 days after inoculation 19 colonies were picked off, none of which proved to be typhoid.

7 days after inoculation 22 colonies were picked off, none of which proved to be typhoid.

11 days after 14 colonies were picked off, none of which proved to be typhoid.

12 days after, 34 colonies were picked off, none of which proved to be typhoid.

14 days after, 23 colonies were picked off, none of which proved to be typhoid.

In all, 18 plates were examined for typhoid bacilli 1 cc.
9959 of water being used in making each plate.

Q. Will you produce and read table X?

A. It is as follows:

9960

TABLE X*

Drainage Canal at Robey St.

Initial colony count sewage bacteria.....	390000
" colon bacilli	4000—6000
" streptococci	2000

B. typhosus, strain (z), was added to this sewage in such numbers that each sac contained approximately 900 typhoid bacilli per cc.

*During the conduct of this experiment, Oct. 9.-23, the temperature of the air ranged from 13°C to 18°C, and of the water from 12.5°C to 14°C.

9961 Q. Will you explain table X?

A. Table X contains the record of an experiment conducted in the drainage canal at Robey Street between October 9 and 23, 1903, the temperature of the air and water and the initial number of sewage bacteria per cc. and the number of colon bacilli and streptococcus being the same as in the three tables just preceding. Bacillus typhosus, the strain previously described as Z, was added to this sewage in such number that each sac contained approximately 900 bacilli per cc.

2 days after inoculation 35 colonies were picked off, none of which proved to be typhoid.

4 days after inoculation 15 colonies were picked off, none of which proved to be typhoid.

6 days after, 17 colonies were picked off, none of which proved to be typhoid.

Q. Will you produce and read table number XI.

A. It is as follows:

9962

TABLE XI*

Drainage Canal at Robey St.

Initial colony count sewage bacteria....113000
" colon bacilli 1000
" streptococci 2000

B. typhosus, strain (y), was added to this sewage in such numbers that each sac contained approximately 25000 typhoid bacilli per cc. The bacilli were added in 50cc of urine from a typhoid patient.

*During the conduct of this experiment, Oct. 18-23, the temperature of the air ranged from 14°C to 19°C, and of the water from 14.5°C to 17°C.

9963 Q. Will you explain table XI.

A. Table XI contains the records of an experiment conducted in the water of the drainage canal at Robey street, between October 18 and October 23, 1903. During this period the temperature of the air ranged from 14 degrees C. to 19 degrees

C. and that of the water from 14.5 to 17 degrees C. The number of sewage bacteria per cc. at the outset of this experiment was 113,000. The number of colon bacilli 1,000. The number of streptococcus 2,000 per cc. Bacillus typhosus, the strain previously designated as strain Y, was added to this sewage in such numbers that each sac contained approximately 25,000 bacilli per cc. The bacilli were added in 50 cc. of urine from a typhoid patient.

2 days after inoculation 11 colonies were picked off, none of which proved to be typhoid.

3 days after 19 colonies were picked off, none of which proved to be typhoid.

5 days after inoculation 12 colonies were picked off, none of which proved to be typhoid.

Q. Will you produce and read table number XII?

A. It is as follows:

9964

TABLE XII.*

Drainage Canal at Robey St.

Initial colony count	sewage bacteria	113000
"	colon bacilli	1000
"	streptococci	2000

B. typhosus, strains (y), was added to this sewage in such numbers that each sac contained approximately 16,800 typhoid bacilli per cc. The bacilli were added in 50 cc of urine from a typhoid patient.

*During the conduct of this experiment, Oct. 18-23, the temperature of the air ranged from 14°C to 19°C, and of the water from 14.5°C to 17°C.

9965 Q. Explain table XII?

A. Table XII contains the record of an experiment conducted in the water of the drainage canal at Robey street, between October 18th and 23rd, 1903. The temperature of the air and water, the initial colony count of sewage bacteria, the number of colon bacilli and streptococcus being the same as indicated in table XI. B. typhosus, the strain previously described as Y, was added to this sewage in such numbers that each sac contained approximately 16,800 per cc. The bacilli were added in 50 cc. of urine from a typhoid patient.

2 days after inoculation 9 colonies were picked off, none of which proved to be typhoid.

3 days after inoculation 17 colonies were picked off, none of which proved to be typhoid.

5 days after inoculation 14 colonies were picked off, none of which proved to be typhoid.

*During the conduct of this experiment, Oct. 25-Nov. 4, the temperature of the air ranged from 6°C to 13°C, and of the water from 9.5°C to 12°C.

9967 Q. Explain table XIII.

A. Table XIII contains a record of an experiment carried out in the water of the drainage canal at Robey street, between October 25 and November 4, 1903. During the conduct of this experiment the temperature of the air ranged from 6 degrees C. to 13 degrees C., and that of the water from 9.5 degrees C. to 12 degrees C.

B. Typhosus, strain Z, was added to this sewage in such numbers that the sac contained approximately 285,000 typhoid bacilli per cc.

One hour after inoculation 49 colonies were picked off from 4 different plates, 41 of which proved to be typhoid.

20 hours after inoculation 54 colonies were picked off from 4 plates, 21 of which proved to be typhoid.

28 hours after inoculation 61 colonies were picked off from 4 plates, 46 of which proved to be typhoid.

2 days after inoculation 69 colonies were picked off from 3 plates, 1 of which proved to be typhoid.

3 days after inoculation —— colonies were picked off, none of which proved to be typhoid.

4 days after inoculation 21 colonies were picked off, none of which proved to be typhoid.

5 days after inoculation 16 colonies were picked off, none
9968 of which proved to be typhoid.

6 days after inoculation 32 colonies were picked off, none of which proved to be typhoid.

7 days after inoculation 36 colonies were picked off, none of which proved to be typhoid.

8 days after inoculation 35 colonies were picked off, none of which proved to be typhoid.

Q. Will you produce and read table XIIIa?

A. It is as follows:

9969

TABLE XIII A.*

Drainage Canal at Robey Street.

Initial colony count sewage bacteria.....240000
" colon bacilli 1000

B. typhosus, strain (z), was added to this sewage in such numbers that each sac contained approximately 285000 typhoid bacilli per cc.

---

*During the conduct of this experiment, Oct. 25-Nov. 4, the temperature of the ai ranged from 6°C to 13°C, and of the water from 9.5°C to 12°C.

9970 Q. Explain table XIII A?

A. Table XIII A contains a record of an experiment carried out in the water of the drainage canal at Robey street, under precisely the same conditions as those recorded in table XIII.

The sac numbered P^2 was inoculated at the same time and in precisely the same manner as P^1, recorded in table XIII.

3 days after inoculation 19 colonies were picked off, none of which proved to be typhoid.

4 days after 18 colonies were picked off, none of which proved to be typhoid.

5 days after 33 colonies were picked off, none of which proved to be typhoid.

6 days after inoculation, 23 colonies were picked off, none of which proved to be typhoid.

7 days after 18 colonies were picked off, none of which proved to be typhoid.

8 days after inoculation 18 colonies were picked off, none of which proved to be typhoid.

9 days after inoculation 41 colonies were picked off,
9971 none of which proved to be typhoid.

10 days after inoculation 37 colonies were picked off, 3 of which proved to be typhoid.

Q. Will you produce and read table XIV?

A. Table XIV is as follows:

9972 TABLE XIV.*

Drainage Canal at Robey St.

Initial colony count sewage bacteria.....240000
" colon bacilli 1000

B. typhosus, strain (y), was added to this sewage in such numbers that each sac contained approximately 857,000 typhoid bacilli per cc. The bacilli were added in 50 cc of urine from a typhoid patient.

---

9973 Q. Explain table XIV?

A. Table XIV contains the record of an experiment conducted in the water of the drainage canal at Robey street, between October 25 and November 4, 1903.

During this period the temperature of the air ranged from 6 to 13 degrees C.; that of the water from 9.5 to 12 C. The number of sewage bacteria in the water at the time of inoculation was 240,000, the number of colon bacilli 1,000 per cc. Bacillus typhosus, the strain previously described as Y, was added to this sewage in such numbers that each sac contained approximately 857,000 typhoid bacilli per cc.

The bacilli were added in 50 cc. of urine from a typhoid patient.

20 hours after inoculation 50 colonies were picked off, 20 of which proved to be typhoid.

28 hours after inoculation 57 colonies were picked off, 45 of which proved to be typhoid.

2 days after inoculation 52 colonies were picked off, 9 of which proved to be typhoid.

3 days after inoculation 56 colonies were picked off, none
9974 of which proved to be typhoid.

4 days after inoculation 35 colonies were picked off, none of which proved to be typhoid.

5 days after inoculation 23 colonies were picked off, none of which proved to be typhoid.

6 days after inoculation 10 colonies were picked off, none of which proved to be typhoid.

7 days after inoculation 25 colonies were picked off, none of which proved to be typhoid.

8 days after inoculation 23 colonies were picked off, none of which proved to be typhoid.

9 days after inoculation 32 colonies were picked off, none of which proved to be typhoid.

Q. Will you produce and read table XV?

A. It is as follows:

9975

TABLE XV.*

Drainage Canal at Robey St.

Initial colony count sewage bacteria......240000
" colon bacilli 1000

B. typhosus, strain (y), was added to this sewage in such numbers that each sac contained approximately 857,000 typhoid bacilli per cc. The bacilli were added in 50 cc. of urine from a typhoid patient.

9976 Q. Explain table XV?

A. Table XV contains a record of an experiment conducted in the water of the drainage canal at Robey street, between October 24th and November 4, 1903.

During this period the temperature of the air ranged from 6 degrees C. to 13 degrees C.; that of the water from 9.5 degrees C. to 12 degrees C., the initial number of sewage bacteria 247,000 per cc., the number of colon bacilli 1,000 per cc. Bacillus typhosus, the strain designated as Y, was added to this sewage in such numbers that each sac contained approximately 857,000 typhoid bacilli per cc. The bacilli were added in 50 cc. of urine from a typhoid patient.

---

*During the conduct of this experiment, Oct. 24-Nov. 4, the temperature of the air ranged from 6°C to 13°C, and of the water from 9.5°C to 12°C.

4 days after inoculation 14 colonies were picked off, none of which proved to be typhoid.

5 days after inoculation 29 colonies were picked off, none of which proved to be typhoid.

6 days after inoculation 12 colonies were picked off, none of which proved to be typhoid.

9 days after inoculation 29 colonies were picked off, none of which proved to be typhoid.

10 days after inoculation 59 colonies were picked off,
9977 none of which proved to be typhoid.

Q. Did you use any control tubes?

A. Yes, sir, I did.

Q. What purpose did you have in using these control sacs?

A. My aim was to discover, if possible, what happened to the sewage bacteria left in such sacs. It is well known that sewage or sewage polluted water removed from its original source and allowed to stand in glass bottles in the laboratory shows a numerous multiplication of bacteria contained in it, thus demonstrating the existence of favorable conditions for the multiplication of sewage bacteria. Under these circumstances, in glass bottles, the number of bacteria in such sewage polluted waters rises into the millions and may even reach tens of millions.

Now, it is well known that in sewage polluted rivers where samples of the water are plated immediately after collection, no such enormous numbers of bacteria are found as in these glass bottle experiments.

In the waters of the Desplaines river and the upper Illinois river, for example, no such numbers of bacteria are observed as in these laboratory observations.

9978 I have already called attention to the fact that an almost steady decline in the number of sewage bacteria and the colon bacteria occurs during the passage of the water down the river, even in the upper stages where the dilution is relatively slight.

In brief, no such multiplication of bacteria is noticed under natural conditions as has long been known to occur in glass bottles in the laboratory.

This is one of the reasons for assuming that the conditions in these glass bottles are more favorable for the life of bacteria generally than in nature, and I have already indicated that one possible reason for this favorable effect is to be found in the nature of the substances dissolved by the water.

It was interesting and important to determine, therefore, whether the sewage bacteria confined in these parchment sacs behaved like those confined in glass bottles or acted more nearly in conformity with what has been observed in natural conditions.

This was the prime object of these control tests. Another reason for making these control tests was to dis-
9979 cover how long the integrity of the parchment sac was
maintained.

Q. Did you prepare any tables showing the result of your analyses of these control tubes for the determination of river bacteria?

A. Yes, sir, I have four tables, tables A, B, C and D, showing the history of such control sacs.

Q. Will you produce and read table A in evidence

A. Yes, sir; it is as follows:

9980

TABLE A.

CONTROLS
LOCKPORT.

No. days in Sac.	Sac No.	Colony count agar 37°	No. B. Coli in 1 cc.	No. Streptococci in 1 cc.
Initial	A_1	470,000	4000-6000	1000
3 days	A_2	2,000	less than 1000	1000
7 days	A_2	660	50	none in 1 cc.
9 days	A_3	2,520	5	none in 10 cc.

9981 Q. Please explain table A?

A. Table A contains the records of the observations upon the bacterial changes occurring in one of these parchment sacs, hereinbefore described, containing water taken from the drainage canal and placed in the drainage canal at Lockport. The initial number of sewage bacteria per cc. was 470,000. In 3 days this number had sunk to 2,000. The initial number of colon bacillus in one cc. was from 4,000 to 6,000. In 9 days the number of colon bacteria had diminished to 5; the number of streptococcus in one cc. was, at the beginning, 1,000; at 9 days no streptococcus was found when 10 cc. of this water was examined.

Q. Will you produce and read table B in evidence?

A. It is as follows:

9982

TABLE B.
CONTROLS
LOCKPORT.

No. days in Sac.	Sac No.	Colony count agar 37°	No. B. Coli in 1 cc.	No. Streptococci in 1 cc.
Initial	K_1	?	1000	2000
3 days	"	8000	10	20
5 days	K_2		6-9	None in 5 cc
6 days	"	1332	6-8	" "
8 days	K_1	11800	7	

9983 Q. Please explain table B?

A. Table B contains the records of observations on one of these parchment sacs. These observations were of the same character as those in the preceding table, containing the water taken from the drainage canal and placed in the drainage canal at Lockport. A decrease in the number of sewage bacteria, colon bacilli and streptococcus was observed.

Q. Will you produce and read table C in evidence?

A. It is as follows:

9984

TABLE C.
CONTROLS
ROBEY ST.

No. days in Sac.	Sac No.	Colony count agar 37°	No. B. Coli in 1 cc.	No. Streptococci in 1 cc.
Initial	E_1	390000	4000-6000	40000
2 days	"	21000	100	20
4 days	"	19500	70-90	1 in 5 cc
6 days	"	70200	50	none in ½ c
7 days	E_2	17200	90-100	none in .1 cc
11 days	"	14600	20	none in 1-5 cc
12 days	E_3	75600	4-10	none in 5 cc
14 days	"	too thick to count	6-10	2

9985 Q. Please explain table C.

A. Table C contains the record of the observations made upon the bacterial changes occuring in one of these parchment sacs containing water taken from the drainage canal and placed in the drainage canal at Robey Street.

I should say, perhaps, that in the case of all of these parchment sacs, both those infected and the controls, the water was taken from the drainage canal at the point where the float was located, and was filled with this water just before inoculation and just before the initial sample was taken.

The initial number of sewage bacteria was 390,000 per cc., the number of B. coli 4,000 to 6,000; the number of streptococcus 40,000.

In 2 days the number of sewage bacteria had fallen to 21,000; the number of bacilli colon to 100; the number of streptococcus to 20.

This sac showed signs of breaking down six days after the beginning of the experiment. This was the earliest that any such change was noticed. The loss of integrity on the part of the sac is first evidenced by an increase in the total number of sewage bacteria and this is followed usually, in several
9986 days by an increase in the number of colon bacillus and streptococcus.

I introduce this table as illustrating the changes taking place in one of those control sacs when the integrity of the sac becomes impaired.

Q. Will you produce and read table D?

A. It is as follows:

9987

TABLE D.

CONTROLS

Robey Street.

No. days in Sac.	Sac No.	Colony count agar 37°	No. B. Coli in 1 cc.	No. Strepto-cocci in 1 cc.
Initial	V_1	240000	800—1000	
20 hrs.	"	327000	700— 900	
28 hrs.	"	326000	800	
2 days	"	122000	100— 200	
4 days	"	17000	20	
5 days	"	16400	7— 8	
6 days	"	17800	5— 6	
7 days	"	7900	8	
8 days	"	5980	9	
9 days	"	7300	6— 8	

9988 Q. Please explain table D?

A. Table D contains a record of the more detailed means of observations upon one of these control sacs containing water taken from the drainage canal at Robey Street and placed in the canal at Robey Street. The initial colony count in this case was 240,000.

Another sample was taken at 20 hours, showing a slight increase in the number to 327,000. In 28 hours the number was 326,000. In 2 days the number was 122,000 and in 4 days the number had fallen to 14,000, and in 9 days to 7,300. The number of colon bacilli in this case remained about the same for the first 28 hours, namely, from 800 to 1,000. In 2 days the number had fallen to from 100 to 200 and in 4 days to 20 per cc.

I regard this experiment as being especially interesting in that it shows a slight initial increase similar to what is observed sometimes in the waters of the drainage canal flowing between Robey Street and Lockport. This very slight initial increase is, however, followed by a rapid decline, and I would call particular attention to the fact that the initial increase does not amount to anything like what is observed in samples of this sewage standing in glass bottles in the laboratory.

To sum up, the conditions shown by these control sacs,
9989 the behavior of the bacteria is shown to be practically
identical with what I have seen reason to believe is the natural course of events in the sewage polluted stream itself. There is at first, perhaps, a slight increase in the number of sewage bacteria, while the colon bacilli apparently hold their own for about 24 hours. There is then a marked and continuous decline in the number of ordinary sewage bacteria as determined by the colony count, and also in the number of colon bacteria and streptococcus, thus simulating in a very precise fashion the changes that take place in the canal and river water.

I regard the evidence presented by these control sacs as confirming altogether the inferences which I have already drawn concerning the naturalness of the conditions in these parchment sacs. The course of events, so far as the death of sewage bacteria and colon bacilli are concerned is precisely the same as what I have been led to consider happens in the river when these sewage bacteria are added to it in Chicago sewage. In both cases there is the same marked diminution in the number of sewage bacteria and in the number of colon bacilli.

9990 Q. Do these tables which you have read into the record
and explained complete the experiment as far as your work is concerned, Professor?

A. Yes sir.

Q. Professor, I show you one of these parchment sacs and ask you to state what it is?

A. It is the sac upon which the observations described in the last table, table D, were made. It was removed from the water at the end of nine days.

Sacs of this character and these dimensions were used throughout the experiment just described.

MR. TODD: I offer this sac in evidence and ask to have it marked "Jordan's Exhibit D."

The sac is marked by the Commissioner as requested by counsel.

9991 Q. When the sac just offered in evidence was taken out
of the water was it intact?

A. It was tested and found intact.

Q. Have you got a table of summaries for the drainage canal at Lockport, based upon the tables that have been offered in evidence?

A. Yes sir, I have.

Q. Will you produce and read the table of summaries?

A. It is as follows:

DRAINAGE CANAL AT LOCKPORT.

Sac. No.	No. typhoid bacilli introduced per cc	10 min.		1 day.		2 days.		3 days.		4 days.		5 days.		6 days.		7 days.		8 days		9 days.		10 days.

Total typhoid found—63.

Total colonies taken after day of inoculation—924.
Total typhoid found after day of inoculation—0.

9993 Q. Will you explain the table of summaries and state what it shows?

A. This table of summaries of the experiment made in the drainage canal at Lockport, on this sheet, headed "Drainage Canal at Lockport," which has just been read in evidence shows the combined results of the several experiments. One sample was taken ten minutes after inoculation, and out of 68 colonies examined 63 were typhoid. One day after inoculation out of 93 colonies examined none were typhoid.

2 days after inoculation out of 165 colonies examined, none was typhoid.

3 days after inoculation out of 242 colonies examined none was typhoid.

5 days after inoculation out of 136 colonies examined none was typhoid.

6 days after inoculation out of 17 colonies examined none was typhoid.

7 days after inoculation out of 119 colonies examined none was typhoid.

8 days after inoculation out of 24 colonies examined none was typhoid.

9 days after inoculation out of 59 colonies examined none was typhoid.

10 days after inoculation out of 110 colonies examined none was typhoid.

9994 The total number of colonies examined after the date of inoculation was 924. In this number no typhoid colonies were found.

Q. Have you a table of summaries for Robey Street prepared from the tables already introduced in evidence?

A. Yes sir, I have.

Q. Will you produce and read the table into the record?

A. It is as follows:

9995

Total colonies taken after 2 days, 1,166. Total typhoid found after 2 days, 3.

9996 Q. Will you please explain what that table shows?

A. The table contains the summarized results of the experiment conducted in the water of the drainage canal at Robey Street. Combining the results obtained from the several sacs the following totals appear:

1 hour after inoculation out of 49 colonies taken 41 were typhoid.

20 hours after inoculation out of 104 colonies taken 41 were typhoid.

28 hours after inoculation out of 118 colonies taken 89 were typhoid.

I may say at this point that the reason why a larger proportion of colonies was found in the 28 hour samples than in the 20 hour samples was because a larger quantity of water was examined or plated and this of course resulted in the appearance of a larger number of typhoid like colonies on the plate.

After 2 days inoculation out of 221 colonies examined 10 proved to be typhoid.

3 days after inoculation out of 142 colonies examined none proved to be typhoid.

4 days after inoculation out of 193 colonies examined none
9997 proved to be typhoid.

5 days after inoculation out of 127 colonies examined none proved to be typhoid.

6 days after inoculation out of 133 colonies examined none proved to be typhoid.

7 days after inoculation out of 139 colonies examined none proved to be typhoid.

8 days after inoculation out of 76 colonies examined none proved to be typhoid.

9 days after inoculation out of 102 colonies examined none proved to be typhoid.

10 days after inoculation out of 96 colonies examined 3 proved to be typhoid.

11 days after inoculation out of 33 colonies examined none proved to be typhoid.

12 days after inoculation out of 75 colonies examined none proved to be typhoid.

14 days after inoculation out of 50 colonies examined none proved to be typhoid.

9998 Q. Professor, you have read into the evidence all the tables and the tables of summaries based upon the experiment which you conducted with parchment sacs, infected with typhoid germs, suspended in the drainage canal, have you not?

A. Yes sir.

Q. Did you make any experiments supplemental to the experiments that you have heretofore introduced into evidence?

A. Yes, I have made some experiments comparing the parchment sacs with celloidin sacs.

Q. Will you describe the manner in which this experiment was made in detail?

A. Large celloidin sacs were prepared by my Assistant Dr. Harris who has had special experience in making these. They were made of the same size as the parchment sacs used in the experiments hereinbefore described and for the sake of having a comparison as to the course of events in these sacs some preliminary tests were made in the laboratory. The parchment sac and the celloidin sac were placed under identical conditions in large glass vessels and a stream of lake water from the tap allowed to pass continuously through the glass vessel so that the temperature was kept constant and the conditions surrounding the sacs were the same. Bacillus typhosus,
9999 the strain previously designated as Y, was added to lake water in such numbers that each sac contained approximately 3,080 typhoid bacilli per cc. The original number of bacteria in the lake water as determined by the usual colony count was 65.

1 day after inoculation of the parchment sac 21 colonies were picked off, 19 of which proved to be typhoid.

In the celloidin sac 1 day after inoculation out of 16 colonies picked off 6 were typhoid.

2 days after inoculation of the parchment sac out of 20 colonies picked off the plate 9 were typhoid.

In the celloidin sac 2 days after inoculation out of 20 colonies picked off the plate 2 were typhoid.

3 days after inoculation of the parchment sac out of 20 colonies picked off the plate 5 were typhoid.

3 days after inoculation of the celloidin sac out of 20 colonies picked off the plate none was typhoid.

4 days after inoculation of the parchment sac out of 20 colonies picked off the plate 1 was typhoid.

4 days after inoculation of the celloridin sac out of 20 colonies picked off the plate 1 was typhoid.

On the 5th, 6, 7, 8, 9, 11, 12, 13 and 15th days after inoculation out of 177 colonies examined, an average of about
10000 20 per day and the same number were examined from the
celloidin sac. In no case, however, was the typhoid bacillus found later than the fourth day.

This experiment shows several points of interest.

1. The validity of the methods of isolation used is again demonstrated by the large proportion of typhoid bacilli obtained in the early days from suspected colonies.

The total number of colonies appearing on the plate was very large on the third and fourth day of the experiment reaching to upwards of 120,000 in spite of the fact that a relatively small number of typhoid bacilli had been added originally, namely 3,080. The isolation of the typhoid bacilli did not prove to be difficult. This seems to me a most striking demonstration of the great value of the special media employed.

(2) In the second place it may be noted that the typhoid bacilli lived about twice as long in this experiment in the lake water as they did in the water of the drainage canal at Robey Street.

(3) In the third place the essential similarity between the course of events in the parchment sacs and in the celloidin
10001 sacs shows that the conditions surrounding the bacilli are
substantially the same whether they are imprisoned in parchment or in celloidin. This was perhaps to be expected since both the celloidin and the parchment have long been used for work in dialysis and since both allowed bacterial toxins and other soluble products to pass freely through their walls while strictly confining the bacilli.

ADJOURNED UNTIL 10:00 A. M., FEBRUARY 5, 1904.

10:00 A. M., Friday, February 5, 1904.

10002 Continuation pursuant to adjournment.

Present, the Commissioner and same counsel representing the respective parties.

PROF. EDWIN O. JORDAN

resumed the stand for further direct examination by Mr. Todd and testified as follows:

Q. Professor, did you make any other comparative experiments?

A. Yes sir, I compared the behavior of sewage placed in parchment and celloidin sacks and kept under the same conditions.

Q. Will you describe that experiment?

A. Fresh sewage obtained from the 56th Street sewer in Chicago was placed in parchment and celloidin sacks, suspended in running lake water in the laboratory as described in the experiment just cited. The initial number of sewage bacteria, as determined by the colony count, was 500,000, the number of B. coli per cc. from 70,000 to 90,000, the number of streptococcus per cc. about 30,000.

A multiplication of the sewage bacteria occurred in the first day, the number in the parchment and celloidin sacks rising to a little over 2,900,000. This was followed in the next 24 hours by a marked decline in the number of bacteria shown in the colony count. The number of colon bacteria and
10003 streptococci remained about the same through the first
3 days and then diminished very greatly.

After 7 days the count showed in the parchment sacks 64,500 bacteria per cc., 1,000 bacilli coli per cc. and 100 streptococci per cc. In the celloidin sack the total number of sewage bacteria was 10,200; the number of B. coli 500 to 700; the number of streptococci 300.

The other examinations made on the 3, 4, 5, 6, 7, 8, 10, and 12th days showed essential similarity between the course of events in the parchment and celloidin sacks thus confirming what was observed in the preceding experiment.

I conclude that the conditions in the parchment and celloidin sacks are substantially identical.

Q. Did you prepare and send any culture media to Professor Russell?

A. Yes sir, the culture medium used by him in his work at Peoria was prepared in my laboratory and sent to Mr. Hastings who was Professor Russell's assistant in the work at Peoria.

Q. State what kind of medium was sent and how it was prepared, briefly?

10004 A. The medium sent was the Drigalski and Conradi medium, the method of preparation of which was described in full in my testimony of yesterday.

Q. From the results of these experiments what conclusion do you draw as to the longevity of a typhoid bacillus in the water of Lake Michigan?

A. It was found by actual experiment under conditions which I believe to simulate closely those in nature that the typhoid bacillus, introduced into unsterilized Lake Michigan water was recovered four days after inoculation and was not found in subsequent examinations made up to the end of the fifteenth day. It is probable that specially resistant individual cells might survive longer than appeared to be the case in the experiment described in my testimony, but in my opinion even such highly resistant individuals, if they did exist, would not live more than about twice as long as the time recorded in these experiments. So that I conclude that 8 to 10 days would be a maximum period of longevity for the typhoid bacillus in the water of Lake Michigan, under natural conditions.

Q. From the result of these experiments what conclusion do you draw as to the longevity of the typhoid bacillus in

10005 the water of the drainage canal?

A. These experiments, of which a large number were made with varying numbers of typhoid bacilli introduced directly into the water of the drainage canal, gave generally uniform results. It was not difficult to discover typhoid bacilli during the first two days. Later than that they were never found either at Lockport or at Robey Street, with one exception. In this anomolous case, 3 typhoid bacilli were isolated on the 10th day from a single plate in a single sack.

Taking into consideration all of the experiments made in the waters of the drainage canal, and assuming, as before, that specially resistant individual cells might exist, which would live twice as long as those found it is my opinion that typhoid bacilli introduced into the waters of the drainage canal, under natural conditions, would not and do not live in that situation longer than four days.

Q. From the result of these experiments, what conclusion do you draw as to the longevity of typhoid bacilli in the water of the Illinois River?

A. Remembering that the upper stretches of the Illinois River are highly polluted with sewage and that considerable additions of sewage are made to the Illinois River at points along its course, I do not believe that bacilli introduced into the Desplaines or upper portion of the Illinois River would live
10006 under natural conditions more than five or six days.

Q. What in your opinion would be the fate of a typhoid bacillus passing from the sewers of Chicago into the Chicago River and thence into the drainage canal and down the Desplaines and Illinois Rivers?

A. It is my opinion that a typhoid bacillus, discharged from the body of a typhoid patient in Chicago and assuming that such discharges were not disinfected so that the bacillus could pass into the sewers of Chicago and thence into the Chicago River and drainage canal, might live as long as 3 or 4 days after leaving the body of the patient.

From what I know of the rate of flow in the drainage canal and in the Desplaines and Upper Illinois Rivers, in my judgment such a typhoid bacillus would perish long before Averyville was reached, even at a period of low temperature and high water.

Q. From a scientific standpoint what value do you attach to this experiment as showing the longevity of a typhoid bacillus in polluted water?

A. I regard the experiment as described as shedding a great deal of light upon the life of the typhoid bacillus under natural conditions.

The results, in my opinion, show quite conclusively that
10007 if any typhoid bacilli survive later than 48 hours after
they have been introduced into the highly polluted waters of the drainage canal they must be highly resistant and very exceptional individuals.

In the experiments as reported there is one instance where typhoid bacilli were found in a single case, on the 10th day.

The singularity of this finding and its isolation from all the other results that were obtained in the course of examination of a large number of sacks, over a long period of time in my opinion demands a special explanation.

The sudden appearance of 3 colonies in the sack after an interval of 8 days, during which no typhoid bacilli were found, although a large number of colonies were examined, points to some unusual occurrence. The most reasonable explanation seems to me to be that at the time when the contents of the sack were heavily infected with typhoid bacilli, during the process of tilting and agitation previously referred to some concrete particle in the sewage to which typhoid bacteria were adhering, was deposited and became dried upon the walls of the sack above the water line. Under these conditions it is my opinion that the typhoid bacillus might remain alive for some time.

Such a dried particle, containing living typhoid bacilli,
10008 might conceivably be washed off from the place where it
had lodged. These typhoid bacilli suddenly introduced into the sack after an interval of 10 days might appear on the plate and be found as in this case. It is certainly difficult to account otherwise for the sudden apearance of three colonies and for their occurring only on one plate. If these typhoid bacilli had remained alive in the water of the sack throughout this whole period, it would be expected that between the second day and the tenth day other resistant individual germs, straggling survivors of the great multitude originally introduced, would also have appeared on some plates and been picked off and identified.

I am inclined to believe, therefore, that this isolated case was due to an accident occurring under the conditions in which the experiment was conducted, and does not indicate that typhoid bacilli would survive as long as ten days in the water of the drainage canal itself. The outcome of all the other experiments made it distinctly opposite to the latter view.

Answering your question then as to the significance of the whole experiment, I would say that in my opinion it indicates a longevity of the typhoid bacillus in the polluted water of the drainage canal of not more than 3 or 4 days.

10009 Q. Does the experiment shed any light upon the longevity of the typhoid bacillus in the sediment of polluted streams?

A. I think it does in this way, that although some sedimentation of the suspended matter occurs in these sacs the tilting and agitating of these sacks each time before the sample was taken led to a thorough mixing of the suspended and sedimented particles. I found no reason for believing that bacilli lived any longer in the sediment of such sacks than freely suspended in the fluid.

Q. What is the behavior of the colon bacillus in soil as compared with its behavior in water?

A. In my opinion it can live much longer in soil than in water, but there is evidence that a certain destruction of colon bacilli takes place also in the soil although not so rapidly as in water.

Q. Is there such a thing as self purification of soil?

A. Yes. I have here a paper entitled "Self Purification of Made Soil, published by Dr. William G. Savage, Bacteriologist to the Cardiff and County Public Health Laboratory and late lecturer on bacteriology, University College, Cardiff."

This paper was published in the Journal of the Sanitary Institute, Volume 24, part 3, 1903, page 442.

In this paper the writer described the experiments made on the continuance of vitality of the colon bacillus in made soils of various kinds. He finds that the colon bacillus lives for 10010 some time in the soil but disappears as times goes on, the ordinary soil organisms invading the material and taking the place of the colon bacillus. He concludes "that the gradual diminution and disappearance of the B. coli in this refuse is of interest from the point of view of specific contamination. This organism, apparently, rapidly dies out in such material. It is a more resistant organism than the typhoid bacillus. It is a fair assumption from this that the typhoid bacillus, if present in such soils, would also rapidly die out and that the danger of *specific* typhoid contamination from building on such made soil can be neglected."

These observations show that B. coli introduced into soil disappears less rapidly, it is true, than in water, but nevertheless shows a tendency to die out.

Q. Does the experiment which you have introduced in evidence shed any light on the life of the colon bacillus in polluted water?

A. It certainly does. The control experiments I have described show that the colon bacillus dies off in polluted water when imprisoned under natural conditions in parchment
10011 sacs. This confirms what has already been noticed regarding the disappearance of B. coli in the running water of the Illinois River and adds weight to the view that the life of the typhoid bacilli under these conditions is very brief, since the colon bacillus is a much hardier organism than the former.

Q. Does that experiment shed any light on the life of the streptococcus in polluted water?

A. Yes, the controlling experiments show that the sewage streptococci die out very rapidly.

Q. To what do you attribute the death of the typhoid bacillus in water?

A. I attribute the death of the typhoid bacillus in such unsterilized water as I have examined to the poisonous action of the products of other microbes.

It is a well established fact that the typhoid bacillus dies off more rapidly in unsterilized water, that is the water containing a normal number of microbes, than in the same water sterilized, that is containing no other form of micro-organisms.

It is also well established that the products of growth of one microbe are often injurious and detrimental to another microbe.

Q. Why is it that the typhoid bacillus will not live as
10012 long in polluted water as in pure water?

A. In my opinion this is because the products of the microbes are present in more concentrated form in the polluted waters than they are in the purer waters. The action of these toxic products in their concentrated form is naturally more intense than where these products are in a diluted condition.

Q. What is your opinion as to whether the typhoid bacillus will live longer in the sediment of a polluted stream than it would in [illegible] water of the same stream?

A. It is my opinion that there would be little material difference.

Q. Why?

A. In the sediment of running streams the typhoid bacilli are in very much the same surroundings so far as I can picture to myself the conditions obtaining in this sediment that they would be in the water of such streams, except that it is fair to suppose that the organic matters on the bed of the stream in the sediment are more abundant. This latter condition would bring it about that the food substances of the saprophytic bacteria would be present in the sediment more abundantly, and that therefore the products of growth of these microbes 10013 would exist there also in a more concentrated form, so that so far as typhoid bacilli would be differently affected by the conditions obtaining in the sediment they would be exposed to the toxic products of saprophytic microbes more intensely than in the water of the stream above this sediment. This condition would tend if anything to cause their death more speedily in the sediment than in the water of the same stream although I do not believe that the difference would be very great.

Q. Will you differentiate between the conditions that obtain in moist soil and the sediment of a running stream?

A. In moist soil the bacilli are not exposed to the action of the toxic products of the microbes with which they are surrounded for the reason that such soluble toxic products can not act upon the bacilli through the intervening air space. A continuous layer of fluid would be needed for a diffusion of the soluble toxic products of these saprophytes and unless the typhoid bacilli were in contact with these, the conditions in an ordinary damp soil would be very different from the conditions prevailing in the sediment on the bottom of a river or pond.

Q. Does the time that the typhoid bacillus will live in moist soil furnish any criterion for its longevity in the sedi- 10014 ment of a running stream.

A. I do not see how it could, for the reasons just stated.

Q. Are the two conditions comparable?

A. They seem to me very different unless one assumes that by moist soil is meant soil saturated or covered with water, in which case the conditions would be substantially the same as these obtaining in the sediment, and the same result might be anticipated.

Q. How long in your judgment will a typhoid bacillus live in a moist soil?

A. Under such conditions as prevail where the contents of privy vaults are spread upon the surface of fields or vegetable gardens typhoid bacilli may in my opinion live for many months. Under these conditions there is sufficient moisture present for them to retain their vitality, and at the same time, owing to the lack of a continuous layer of fluid, any toxic products of other microbes can not diffuse through the mass and injure the typhoid bacilli.

Q. Would the fact that the typhoid bacillus lived several months in moist soil justify the assumption that it would live for the same length of time in the sediment of a river?

A. By no means.

Q. Will you please give your reasons in full for the answer
10015 you have just given?

A. The conditions in ordinary moist soil and in the sediment of a river differ practically since in ordinary moist soil, if I understand what is meant by that term, there is slight opportunity for the action of the soluble toxic products of saprophytic bacteria upon the typhoid bacilli, and, as I have stated, there is reason to believe that it is the effect of these soluble products upon the typhoid bacillus in water that causes the death of the latter. The poisons of these bacteria could not influence so profoundly the longevity of the typhoid bacillus in soil.

The experiments by Dr. Savage that I have already cited, on the disappearance of the colon bacillus from soil indicate, however, that the typhoid bacillus will probably die out in soil, like its more hardy relative the colon bacillus, although less speedily than in the sediment of a river or in polluted water.

Q. Do you know of any bacteriologist since the beginning of bacteriology that has demonstrated by any experiment that typhoid germs do live in the sediment of lakes or rivers for a long period of time?

A. I do not.

10016 Q. Professor, Mr. Fuller, in his testimony, on page 4218 of the transcript of the record, a copy of which I have, stated that "There were observers over in Switzerland who made such examinations with positive results showing the presence of typhoid germs in the sediment of Lake Geneva, I think also Lake Zurich." Do you know anything about these observations to which Mr. Fuller referred?

A. I know of the observations on Lake Geneva, to which I suppose this statement refers. I have made an examination of the literature to discover something regarding the presence of typhoid germs in the sediment of Lake Zurich but I have found nothing that bears directly on this point.

Q. Will you please state the facts and circumstances as you know them in connection with these observations?

A. The observations on Lake Geneva were reported by an investigator named Lortet at the International Medical Congress in Berlin between the 4th and 9th of August, 1890.

10017 These investigations were published in the Centralbl f. Bakteriologie, 1891, Volume 9, p. 709, entitled "Pathogenic Bacteria of the Deep Mud in Lake Geneva."

The observations as reported covered the examination of slime taken from a depth of 40 to 50 meters, 2 kilometers from the shore. This deep mud was found virulent when inoculated into animals and was more virulent than that taken from near shore. The material taken 200 meters from shore in the water 4 meters deep was sterile, and animal experiments gave negative results. The statement is made that the staphylococcus pysogenes aureus, the tetanus bacillus, the bacilli coli and the bacillus typhosus were isolated from the deep mud 2 kilometers from shore as already alluded to.

No statements are made as to the methods of identification of these microbes. This was before the Widal tests was used for the identification of the typhoid bacillus and in view of the fact that no statements are made by this authority regarding his other methods of identification the mere report of finding these organisms was not a satisfactory one. 10018

It may be added that the author makes a statement that every part of the lake from which material for investigation was taken contained chemically very pure water. Assuming that the pathogenic bacteria isolated were correctly identified, which seems rather a violent assumption in view of all the premises, there are no data as to the length of time that these organisms had been present in the sediment.

I may add that Loeffler in his treatise on Water and Microorganisms, one of the leading German authorities on questions of this sort, in mentioning Lortet's report of the finding of the typhoid bacilli in the slime of Lake Geneva (page 592) puts an interrogation mark after the name typhoid bacillus, indicating his skepticism as to the correct identification of this microbe. Personally I share this skepticism and am unable to assume, in view of the facts given by Lortet in his report, that this identification was correctly and satisfactorily accomplished.

Q. In the light of the present knowledge in regard to bacteriology what importance do you attach to these observations in connection with Lake Geneva?

10019 A. I can attach no importance to them so far as shedding any light upon the logevity of the typhoid bacillus in sediment, since even supposing that the identification were correct there is nothing to indicate how long such bacilli had been present in the sediment of Lake Geneva.

Adjourned until 2:00 P. M. same date, February 5th, 1904.

2:30 P. M., Friday, February 5, 1904.

10020 Continuation pursuant to adjournment.

Present, the Commissioner and same counsel representing the respective parties.

PROF. EDWIN O. JORDAN

resumed the stand for further direct examination by Mr. Todd, and testified as follows:

Q. Mr. Fuller, in his testimony, (page 4218 of the transcript of the record, a copy of which I have) in answer to the question "Had it ever been demonstrated by a bacteriologist that typhoid germs have lived in the sediment of a running stream" answered "It has been demonstrated that they have lived for a long time in the sediment of lakes, and I do not consider that there is any weakness in the process of reasoning by which one steps from a lake to a river, provided, of course, that each of

these waters are live waters and not subject to aseptic actions." The further question "By whom has it been ascertained that the typhoid germ has been found to live in the sediment of a running stream or lake" Answer "There are several over in Switzerland who made such investigations with a positive result
showing the presence of typhoid germs in the sediment
10021 of Lake Geneva and I think also Lake Zurich." I will
ask you do you regard the observations in Lake Geneva as quoted by Mr. Fuller as a demonstration that the typhoid bacillus has been found to live for a long time in the sediment of lakes?

A. I certainly do not.

Q. Will you please give your reasons?

A. As already stated there are grave objections to regarding Lortet's investigations in Lake Geneva, first as demonstrating that the genuine typhoid bacillus was found in the slime at the bottom of the lake as alleged. Second, that there are no data as to the length of time such bacilli had remained in the slime, assuming this author's identification to be correct.

Q. Mr. Fuller, in his testimony (page 4219 of the transcript of the record which I have) in answer to the following question "Is not the length of time that a typhoid bacillus will live in a sediment more a matter of assumption than a matter of demonstrated proof? Answer "I consider that it is a very clean cut demonstration where the typhoid fever germs may die and have continued to live in the sediment of running streams."
Question "For what length of time"? Answer "I should
10022 say for a month or more, possibly in cases for years."
Question "Who has demonstrated that it has ever lived a year"? Answer "I think that the conditions existing in a moist soil in many rural places in this country where typhoid fever prevails from time to time is proof that typhoid fever germs in the presence of moisture can live for such a term. If that were not so then there would be an elimination of typhoid fever absolutely through the rural districts of this and all other countries." I will ask you, professor, whether you know of any experiments or observations that have demonstrated that typhoid fever germs may and do and have continued to live in the sediment of running streams for a period of a year and

whether the conditions of moist soil furnish any criteria for the longevity of the typhoid bacillus in the sediment of a running stream?

A. In reply I will say that I do not know of any experiments or observations that demonstrate that typhoid fever can live in the sediment of running streams for a period up to a year.

In my opinion the conditions obtaining in moist soil are very different from those obtaining in the sediment of running streams, and I see no reason whatever for believing that
10023 the typhoid bacillus will live in the sediment of running streams for a similar period.

Q. Do you know of any one who has gone into the question of the life of the typhoid bacillus in natural waters and has made any experiment as extensive as the experiments which you and Professor Zeit and Professor Russell have made and which you have introduced in evidence?

MR. JEFFRIES: I object to the question for the reason that it leaves it to the witness to determine comparatively speaking the length and extent of the investigations that have been had upon the subject in question and does not require of the witness to state or give his understanding as to the extent, duration and limit of the investigations that have been made by others than himself and the persons associated with him in the investigations in question, and that it is for the court to determine and not this witness as to whether or not the investigation made by him and his associates is as thorough or is as extensive and complete as the examinations and investigations that have been made by others upon the same subject.

A. I do not know of any published report of an experi-
10024 ment of this character so extensive in detail as the one that has been introduced.

MR. JEFFRIES: I move to strike out the answer for the reason that it is based upon what the witness has learned from published reports and for the reason that the witness states that in those published reports no investigations which have been made, wherein the details are set out, were such as were made in the investigations by this witness and his associates, and I move to strike it out for the reason that the evidence here shows, and all published reports show, that it has never been considered necessary by competent and reputable and distinguished bacteriologists, sanitarians or epidemiologists to set out in the report published to the world the exact manner and detail in which all of the experiments at the various experimental stages were made, and I move to strike it out for the reason that it is an attempt to reflect discredit upon all reports made by sanitarians and investigators wherein the details of the analyses are not set out, and for the reason that it is incompetent, irrelevant and immaterial and insufficient and is not responsive to the question.

MR. TODD: In reply to so much of counsel's objection
10025 as he claims is based upon the record in this case, I desire to state that the record does not show the facts to be as counsel has stated them to be disclosed by the records.

Q. How near does the experiment named by you approach natural conditions?

A. I have already indicated it as my opinion, and to this I firmly hold, that the conditions under which this experiment were conducted imitate natural conditions as closely as it is possible to imitate them in the present state of bacteriology.

Q. Are the conditions of the experiment which you have introduced more or less favorable to the longevity of the typhoid bacillus than the natural conditions of the water in which the experiment was made?

A. These conditions are, in my opinion, so close to natural conditions that I am unable to say whether they are more or less favorable. The difference is, in my opinion, insignificant.

Q. What reasons, if any, have you for supposing that the conditions described in your experiment, closely simulate natural conditions?

A. The bacteria in the parchment sacks are exposed to
10026 similar conditions of temperature. They are also exposed to the action of the substances present in the sewage and such substances formed by the multiplication of saprophytic bacteria within the sacks. The diffusion that takes place through the walls of the parchment sacks allows soluble substances to pass through, both those inside the sack to pass

out and those outside to pass in where the osmotic conditions are suitable.

These sacks have been tested with solutions of dyes and acid and alkali and have been found permeable. Thus, if a solution of litmus be placed in a glass vessel and a parchment sac containing dilute acid be suspended in this solution of litmus, the acid will pass through the walls of the parchment sac and will cause the blue color of the litmus to change to red. Conversely, if a litmus solution be placed inside the sac and the sac suspended in the acid solution, the acid will pass through the parchment into the sac, changing the litmus to red color. In either case the interchange of substances between the parchment sac and the fluid outside continues until a state of equillibrium is established. So that the contents of the 10027 parchment sac suspended in the water of the drainage canal are in free communication with the waters of the drainage canal itself, and interchange of food substances and other toxic substances being possible.

For these reasons it is my judgment that the conditions of the experiment similate with great exactness natural conditions.

Q. How do the conditions of this experiment differ from those of the glass bottle experiments such as have previously obtained in the laboratory experiments on the longevity of the typhoid bacillus?

A. In the glass bottle experiments substances are dissolved from the glass by the water, and these favor continued vitality on the part of the microbes contained in the water. These substances dissolved from the glass are not found in the case of the parchment sac experiments.

Q. Is there any reason for anticipating greater or less longevity on the part of the typhoid bacillus in the glass bottles than under the conditions of your experiment?

A. I should anticipate that typhoid bacilli would live longer in glass bottles than in parchment or celloidin sacs.

Q. What do the facts show?

10028 A. The experiments on the longevity of the typhoid bacilli that have been made in glass bottles in the laboratory and have been previously published by other investigators, show a generally greater longevity than that found in the conditions obtaining in my experiment.

Q. What is your opinion, based upon all the knowledge which you possess, as to whether typhoid bacilli coming from the sewers of Chicago and entering the drainage canal, could survive the journey from Chicago to St. Louis, a distance of 347 miles, and be a danger and a menace to the inhabitants of the City of St. Louis using the water of the Mississippi River for drinking and domestic purposes?

A. It is my opinion that typhoid bacilli could not survive the journey from Chicago to St. Louis, under the conditions just mentioned, and I do not believe that such typhoid bacilli would arrive in the Mississippi River in a condition that they could be called a menace to the inhabitants of St. Louis.

Q. Are you familiar with the settling basins employed by the City of St. Louis?

A. I have observed these settling basins at the St. Louis waterworks on a number of occasions.

10029 Q. Do the settling basins at St. Louis afford any protection to the citzens of St. Louis against infectious matters in the waters of the Mississippi River at the Intake Tower?

A. In my opinion they do afford a very considerable protection against infectious matters that may be present in the waters of the Mississippi River at the Intake Tower. It appears from the testimony of Professor Ravold in this case that 75 per cent. of the bacteria are removed in the sedimentation basins.

In my opinion the water supplied to St. Louis is much safer than it would be if settling basins did not interpose between the raw water of the Mississippi River and the consumer.

Q. Are the settling basins of St. Louis any protection to the citizens of St. Louis against the sewage of Chicago?

A. I do not believe that any dangerous elements entering the sewers of Chicago reach as far as the Mississippi river and if that is the case I do not see how the settling basins of St. Louis could protect against the sewage of Chicago.

Q. If none of the sewage in its dangerous state reaches the city of St. Louis from Chicago, from what source in your opinion comes the infectious matter which these settling basins eliminated? 10030

A. It comes, in my opinion, from places nearer to St. Louis than Chicago, places situated on the Missouri, Mississippi and Illinois rivers, within five or six days flow from the Intake Tower.

Q. When a settling basin holds a sufficient amount of water to supply the city for a period of thirty days, and as the water is taken out for domestic uses, raw water is immediately supplied, and typhoid fever should prevail among the people using said water, what is your opinion whether such a condition justifies the assumption that because the reservoir holds a supply for a period of thirty days, that a typhoid bacillus will live in that water for such a period

A. In reply I will state that I should wish to investigate thoroughly the conditions surrounding a community so situated and to determine to my satisfaction that the water supply in the settling basin was the source of the typhoid fever prevailing among the people. Some further points would also have to be considered.

As I understand the situation described it is not true that all the water pumped into the settling basin would remain there for a period of thirty days, allowing that length of time for typhoid bacilli to die out, but on the contrary water would be drawn continually from the reservoir during this period of thirty days. 10031

Such being the case it seems to me obvious that not all of the water drawn from the reservoir could have remained in the reservoir for a period of as long as thirty days. Some of it in fact may be drawn from the reservoir within a very short time after its entrance into said reservoir, possibly within 24 or 48 hours of its being taken from the river. Any typhoid germs introduced in this way might be drawn out from the reservoir without having remained in it for a period as long as that mentioned.

It does not seem to me to follow because a reservoir or settling basin holds a thirty days' supply that all typhoid bacilli introduced into the reservoir remain there for thirty days.

Q. Do you know of any experiments dealing with the longevity of cholera and anthrax bacillus in aquaria?

A. Yes sir, I know of some experiments on the longevity of cholera and anthrax bacilli in aquaria.

Q. Will you please give them?

10032 A. These were by Dr. L. Hoeber from the Hygienic Institute at Wurzburg Centralbl f. Bakt., 1895, Bd. XVII, p. 443.

I quote from this paper by Dr. Hoeber:

"The result of my work is therefore as follows: Cholera as well as Anthrax bacilli can remain alive in aquaria, therefore, under conditions which correspond closely to those in nature, no longer, or at least, only a short time longer, than in the different waters in which up till now their longevity has been investigated. Whether by mixing with blood (sewage, drainage), etc., the results would be otherwise, is still to be investigated. In experiments by Professor K. B. Lehmann, where anthrax broth cultures were added to the aquaria, the bacilli perished with accompanying luxuriant increase of green desmids."

Q. Have you had any experience in the investigation of epidemics?

A. Yes sir, I have investigated several epidemics of typhoid fever in this country.

Q. What epidemics have you investigated?

A. Recently I have investigated the epidemic at Ithaca, New York, and at Butler, Pennsylvania.

Q. Professor, have you made a special study of epi-
10034 demics?

A. I am generally familiar with the classical epidemics of cholera, typhoid fever, etc., as described in the literature. I have also known of the conditions surrounding a number of epidemics of typhoid fever occuring in this country and have visited the places where these outbreaks have taken place. I have also, as already stated, investigated in considerable detail the circumstances of several of the most important outbreaks of typhoid fever that have occurred in the United States.

Q. Will you describe the epidemics that you have investigated?

A. The epidemic of typhoid fever that occured at Ithaca, New York, in February and March 1903, was one of the most extensive that has ever been reported in this country.

In a population of about 15,000 inhabitants there occurred during a period of about two months some 1,300 cases and 78 deaths. A large number of these cases and deaths took place among the students of Cornell University.

It was suspected from the natural history of this outbreak that the public water supply was in some way implicated.
10034 The peculiar distribution of typhoid fever in the town at once drew attention to the significant incidents of the infection. That portion of the town supplied with the main public water supply developed a large number of cases of typhoid fever while Cornell University campus and some surrounding houses which were supplied from another source remained entirely exempt from the disease. The rest of the town suffered severely. The University buildings and some 52 houses on or near the campus and about 17 houses at Cornell Heights remained free from the fever, although all through the rest of the town especially in the student boarding houses situated close to the campus many hundreds of cases of typhoid fever developed. With one exception the women students of the Sage college located on the campus numbering over 200 were not affected.

On investigation the distribution of water supply in town it was found that the maximum number of cases of typhoid fever developed in that portion of Ithaca supplied with water taken from a small stream known as Six Mile Creek. The water shed of this creek was found, on investigation, to be in
10035 a very objectionable condition. Loosely constructed outhouses and privies were situated along the bank of this creek and there were a number of opportunities for pollution. It was not found possible to trace the precise origin of the infection of the water supply, although several possibilities existed, any one of which might have given rise to the outbreak. The Ithaca epidemic was undoubtedly a water borne infection as shown by the distribution of cases in strict accordance with the various water supplies.

Q. Were these different sources of infection of an urban or a rural character?

A. They were such sources of infection as one sees frequently in the country districts of this country; over-hanging privies and water closets close to the banks of streams. There seemed to be no supervision of the water shed in the way of guarding against contamination by bands of laborers. I should call the sources of infection in this case distinctively and peculiarly rural.

Q. What other epidemics have you investigated recently, Professor?

A. The one at Butler, Pennsylvania, occurring in November, December and January, 1903 and 1904.

10036 Q. You have investigated that epidemic since you began to testify in this case have you not?

A. Yes sir.

Q. Will you describe the Butler epidemic?

A. The Butler epidemic first became apparent early in November 1903, and has resulted up to the present time in some 1,400 cases and about 110 deaths.

In the number of deaths therefore the Butler epidemic ranks with that at Plymouth, Pa., in 1884, as one of the most extensive reported in the sanitary history of the United States.

The town of Butler contains about 16,000 inhabitants and is supplied with water drawn from Connoquenessing Creek. Owing to the rapid increase in the population of the town, the demand for water has increased very rapidly and the water supply, which is in the hands of a private company, has not been adequate to the needs of the expanding community. The water was pumped from a point in Connoquenessing Creek about a mile and a half above the town and for some time has been filtered by open gravity filters into which a coagulent, basic sulphate of aluminum, was ordinarily introduced. These filters were thrown out of service between October 20th and 10037 31, 1903, in order to permit of some connections being made between the new high service pump and filtered water basin, and also to join some new piping with the old low service piping. These changes necessitated the emptying of the filtered water basin and the shutting down of the filters that supplied it until the changes were completed.

There seems no doubt that that this interruption of the filters during this period in the latter part of October was responsible for the great outburst of typhoid fever that followed.

There are abundant opportunities for infection on the Connoquenessing water shed. No fewer than 17 cases of typhoid were found to have existed on this water shed from the beginning of July, 1903 to the end of the year. Apparently the waters of Connoquenessing Creek and some of its tributaries had been highly charged with infectious matter during a considerable period, and it simply required the putting out of commission of the filters to precipitate the catastrophe.

10038 Here as in the case of Ithaca the water supply was definitely implicated from the outset by the topographical incidence of the disease. That part of Butler lying south of the Baltimore & Ohio Railroad tracks and known locally as Springdale remained almost entirely exempt from the infection throughout the epidemic. This territory forms topographically a part of the town of Butler and apparently differs from it only in the fact that it is not provided by city water, but receives its supply from a number of artesian wells. In this part of the town, with a population of about 2,500, it is stated on high authority that but few cases developed and these among persons attending school or working in that portion of Butler supplied with the Connoquenessing water.

Q. Was the source of infection in the Butler epidemic attributed to urban or rural population?

A. To rural population. These houses on the Connoquenessing water shed in which the cases of typhoid fever occurred were typical small American farm houses and shanties provided with loosely constructed privies. Discharges from the bodies of patients were thrown, with little attempt at disinfection, either into these outhouses or directly upon steep rocky

10039 hill sides where they remained until washed down into the creek by heavy rains. The class and character of the infection were such as pertain distinctively to rural conditions.

Q. What other epidemics are you acquainted with besides the two you have detailed?

A. I was at Lowell for a short time with Professor Sedgewick when he investigated the outbreak of typhoid fever in that city, to which reference has been made in his testimony. I visited Stamford, Conn., during the progress of a considerable epidemic of typhoid fever in that town, due to an infected milk supply. I have also known something about the conditions in the city of Chicago, leading to excessive prevalence of typhoid fever in this city.

Q. Are you acquainted with the Plymouth epidemic?

A. I know of the Plymouth epidemic only from what is found in the printed reports of this outbreak. This is perhaps the most famous epidemic of typhoid fever in the sanitary annals of this country. The severity of the infection as well as the large number of persons attacked and the large number of deaths resulting from the epidemic make it one of the most celebrated epidemics of which there is any record.

10040 Q. Was the Plymouth epidemic an urban or a rural infection?

A. This also was a case of rural infection. The outbreak was traced to an infection of the water supply with the dejecta from a single typhoid patient which had been thrown out on the hillside and allowed to accumulate near one of the feeders of the reservoirs supplying the town with water. There the most of the infectious material remained until washed down into the stream by spring floods and melting snows.

Q. What was the cause of the Lowell outbreak?

A. The Lowell outbreak was traced by Professor Sedgewick to the infection of Stony Brook, a small feeder of the Merrimac River, entering the Merrimac River a short distance above the intake of the Lowell waterworks. Several cases were found by Professor Sedgewick, on investigation, to have been a possible source of the infection of the water of Stony Brook, and the history of these cases corresponded in time and other circumstances with the conditions surrounding the outbreak of typhoid fever in Lowell.

Q. What was the character of that infection as to whether or not it was rural or urban?

A. These also were cases of infection by rural popula-
10041 tion, if as I understand is meant by that, a population not provided with sewers but isloated in character and draining by individual outhouses or by over-hanging privies directly into brooks or other small streams. The infection at

Stony Brook was very similar in character to that already denoted as occurring at Ithaca, Butler and Plymouth.

Q. What other epidemics aside from those you have referred to are you acquainted with?

A. I am familiar with some of the well known instances recorded in the books on sanitary subjects and water supply. One of the very remarkable outbreaks of epidemic disease, due to infected water, was that occurring in Hamburg, Germany, from Asiatic cholera. Although Hamburg itself was .severly afflicted with cholera the neighboring suburb of Altona remained almost entirely exempt although its water supply was derived from the River Elbe below the point at which the sewage from Hamburg entered. The water supply of Altona was, however, safeguarded by the interposition of sand filters which proved effectual against the highly polluted river water. The difference between the two water supplies was so marked
10042 that in streets near the boundary line between Hamburg and Altona supplied partly by Hamburg water (unfiltered) and partly by Altona water that had passed through sand filters, the distribution of cholera cases corresponded exactly with the distribution of the water supply. Cholera cases occurred in houses supplied with the Hamburg water while the houses supplied with Altona water remained exempt from this disease.

This is regarded by sanitarians as one of the most striking demonstrations ever given of the connection between a polluted water and an outbreak of epidemic disease.

Other classical epidemics of water borne disease in Europe are the one at Lausen, Switzerland, where typhoid fever was caused by the polluted spring water; the outbreak of cholera in London due to the use of water from the Broad Street Pump; several outbreaks of typhoid fever in England, namely at Cotterham, at Worthing and in the valley of the Tees.

ADJOURNED until Tuesday, February 9th, 10:00 a. m.

10043 10:00 a. m., Tuesday, February 9, 1904, Continuation pursuant to adjournment.

Present, the Commissioner and same counsel representing the respective parties.

PROF. EDWIN O. JORDAN

resumed the stand for further direct examination by Mr. Todd, and testified as follows:

Q. What does the term epidemiology embrace?

A. As I understand it the term epidemiology embraces the study of vital statistics, the interpretation of these statistics; a consideration of the weight to be placed on the data of bacteriology and chemistry; a study of the modes of causation of various forms of infectious disease; a study of the sources and intensity of infection; a study of the relative incidence of disease upon rural and urban populations and the modes of spread of disease in urban and rural districts; a study of the relative share of urban and rural populations in polluting the public water courses; a study of the vehicles of infection in any given
community, such as food, drink, air infection, etc.; a
10044 study of the character and manner of differentiation of
various infectious diseases.

As I understand these and kindred topics are included within the scope of what is sometimes known as the science of epidemiology.

Q. Is there any distinct difference between an epidemiologist and a sanitarian, or are the terms synonimous?

A. As the terms are used at the present time they are often used interchangeably, epidemiology, as I understand it, being one branch and a very important branch of sanitary science.

Q. Please state what you mean by vital statistics and what sanitary significance do they have to an epidemiologist or sanitarian?

A. By the term vital statistics is meant all the available information regarding the number of persons attacked by various diseases, the number of persons dying of each disease or each class of diseases, the factor involved in the age and sex distribution of the population, and the influence of occupation and the factor so far as these affect the prevalence and fatality of disease:

In short, all the information that can be obtained in a sta-
tistical form regarding the morbidity and mortality in
10045 a given district or population.

As regards the sanitary significance that vital statistics have for the epidemiologist, I may say that it is generally considered that a correct understanding of vital statistics forms the necessary and proper foundation to the science of epidemiology. The accurate collection of facts regarding the prevalence and fatality of disease must perforce constitute the basis for any sound deductions as to the spread, causation and maintenance of epidemic conditions.

Q. Explain what you mean by the interpretation of vital statistics?

A. Assuming that the facts that furnish the basis for a study of vital statistics are accurately collected and tabulated, there remains the very important question of the interpretation of such statistics. It is not a matter of indifference how the figures so collected are viewed by the statisticians. Statistical pitfalls are numerous and certain fallacies of interpretation exist, the introduction of which may vitiate any conclusion drawn from figures in themselves exact.

To give an illustration: It is very commonly assumed that
the death rate in a city, that is the number of deaths per
10046 thousand population annually is a correct measure of
the healthfulness of such a city. The death rate, however, among individuals of different ages and of different nationalities varies so much that the crude death rate, that is the death rate per 1,000 population, without regard to age or sex distribution, or to racial characteristics, is often very far from affording any indication of the healthfulness of a given community.

Thus, that population having in it a large per cent. of infants or of aged individuals would have a larger number of deaths per thousand population than a community having a larger proportion of the individuals between the very resistant ages of say 15 and 40.

So in comparing one section of a city with another, the racial distribution of the population, that is to say the prevalence of persons of American born or German or Irish or Russian, parentage will affect the death rate very profoundly. In the interpretation of vital statistics, therefore, the interpretation of the crude facts observed is a matter of the utmost importance.

Q. In what way do racial characteristics manifest themselves?

A. It is well known that certain races of mankind mani-
10047 fest inborn powers of weakness or of resistance to the onslaughts of various forms of disease.

For example, persons of Irish parentage are much more liable to consumption and pneumonia than Russian and Polish Jews. Any city or any section of a city, therefore, having a large proportion of its population of Irish parentage, will have a higher death rate from consumption and pneumonia than a district containing few Irish and a larger proportion of Russian and Polish Jews.

Q. How much importance do you attach to the proper interpretation of vital statistics?

A. I attach the very highest importance to the interpretation of such statistics. The facts in themselves are meaningless unless correctly interpreted.

Q. What do you understand to be a proper interpretation of vital statistics?

A. An interpretation taking into account all the known factors of every kind that may have had a share in bringing about the conditions observed. Unless these factors are considered there can be no such thing as proper interpretation.

Q. Are you acquainted with the method known as the mortality percentage method?

10048 A. I understand that you mean by the expression "mortality percentage method" the method of representing the prevalence or fatality of a disease by reckoning the ratio of deaths from that disease to the total deaths occurring in that population during the period under consideration.

Q. What is your opinion as a sanitarian and epidemiologist as to the correctness of employing the mortality percentage methods for the purpose of ascertaining the prevalence of a given disease in a community?

A. It is my opinion that the mortality percentage method may and often does fail to give correct information as to the prevalence of a given disease in a community during any specified period.

Q. Is the mortality percentage method the method adopted and approved by the sanitarians and epidemilogists of this country and of Europe?

A. I think on the contrary this mortality percentage method is distinctly not in favor among sanitarians and epidemiologists here and in Europe.

The following is an excerpt from Newsholme's Vital Statistics, published in 1899, page 186.

This book is recognized as the leading authority in the
10049 English language on the question of vital statistics.

The statement is as follows:

"The mortality from any given disease or group of diseases may be stated as a proportion to the deaths from all causes. This method is, however, essentially fallacious, as it constitutes a ratio between two factors, of which both are variable, viz., the mortality from the specified disease, and the mortality from all causes. Dr. Ransome gives the following example of its fallacious character. Suppose a town of 1000,000 with 2,000 annual deaths, of which 500 are caused by phthisis. Here the general death rate is 20 per 1000; the death rate from phthisis is 5 per 1000 living and the death from phthisis forms one-fourth of the total deaths. In another town, having the same population, the total deaths are 4,000, and therefore the death rate 40 per 1,000 inhabitants; the deaths from phthisis are 1,000, and therefore the death rate from phthisis is 10 per 1,000; but the proportion of the phthisical to the total mortality is one-fourth, as before. In the second town, however, there is by the latter test apparently no worse condition, so far as phthisis is concerned, than in the first, though matters are really twice as bad.

In annual reports of medical officers of health the zym-
10050 otic mortality is frequently stated as a percentage of
deaths from all causes. Thus, if in one year the zymotic mortality forms 11 and in the next year 15 per cent. of the total mortality from all causes, it is evident that the relative mortality might be increased either by a diminution in total deaths or an increase of zymotic deaths, though the inference to be drawn in the two cases would be very different.

It is occasionally convenient to know the percentage of deaths due to different causes, in order to estimate the relative magnitude of the different causes of death; but this method can not be employed with propriety in comparing one community with another, or even in comparing the records of the same community in sucessive years."

Then again on page 336 of this book the paragraph headed "Fallacies arising from stating deaths in proportion to total deaths."

Which statement follows:

"These have already received consideration (pp. 124, 186). They present themselves under two heads. The deaths at one age are stated in proportion to the total deaths at all ages; or the deaths from one cause are stated in proportion to the total deaths from all causes. In both cases the same 10051 fallacy is involved. A relationship is attempted to be established between the two factors both of which are variable in value. An alteration in the total deaths on one hand, or in the deaths at one group of ages or from one cause on the other hand, might equally affect the proportion between the two, though the conclusion to be drawn in the two cases would by no means be necessarily identical."

I think that these statements of Dr. Newsholme represent the correct opinion among sanitarians and epidemiologists, regarding the validity of the mortality percentage method. This method involves an obvious fallacy.

Q. Does the mortality percentage method receive your approval as a sanitarian and epidemiologist?

A. For the reasons already set forth I do not consider or regard this method as shedding a true and proper light upon the relative incidence of disease in a community.

Q. What reasons have you for opposing the mortality percentage method as not furnishing the correct rule for the interpretation of vital statistics?

A. I will give an illustration of the fallacious character of this method.

In the city of New York, with a population of 955,921, in the year 1871, there were, according to the records of 10052 health for that City, 26976 deaths, 251 of these being from typhoid fever. The per cent. of the typhoid fever deaths to the total number of deaths was 0.93. The death rate per 10,000 inhabitants from typhoid fever was in this same year 2.62.

In the year 1898, in the City of New York, with a population of 2,048,830, the total deaths were 40,438, of which 376 were typhoid fever.

The typhoid fever deaths were again 0.93 of the total deaths, but the death rate per 10,000 inhabitants was 1.83. In other words, in these two years, 1871 and 1898, the percentage mortality of typhoid fever was the same but there was actually a decrease in the typhoid fever rate from 2.62 per 10,000 to 1.83 per 10,000, or a real reduction of over 30 per cent.

The mortality percentage method fails utterly to show that this reduction of over 30 per cent. has occurred.

A still more striking instance of the failure of the mortality percentage method to reveal such relations is shown in the annual reports of the health department of the City of Boston.

10053 In the year 1871, with a population of 258,032, the total number of deaths from all causes were 5,888, of which 176 deaths were from typhoid fever. The percentage of typhoid fever deaths to those from all causes was 2.99. The death rate per 10,000 inhabitants being 6.82.

In the following year, 1872, with a population of 265,764, the deaths from all causes were 8,090, of which 229 were from typhoid fever. The typhoid fever deaths were in this year 2.83 per cent. of the deaths from all causes. Thus, it would appear from the mortality percentage method that there had been a reduction in typhoid fever in that community, although the actual number of deaths had risen from 176 to 229.

This apparent reduction was of course caused simply by the remarkable increase in the number of deaths from all causes, namely from 5,888 to 8090. The death rate from typhoid fever, reckoned per 10,000 inhabitants, gave, however, a truer indication of the real conditions and showed that instead of diminishing from 1871 to 1872 typhoid had actually increased from 6.82 to 8.62.

Here again the mortality percentage method gives an entirely incorrect and erroneous conception of the real amount of mortality from typhoid fever.

Q. Professor Sedgwick, in answer to this question, page
10054 3540, of my copy of the record: "What method of ascertaining the percentage did you use in fixing the increase in typhoid fever in St. Louis," answered, "I used the method known as that of mortality percentages in which the typhoid fever mortality is compared with the total mortality of any given district. This method is a common one among sanitarians and students of vital statistics and is regarded as on the whole the most accurate, inasmuch as it takes no account of the population, always a dubious and uncertain factor, while the number of deaths is always or is usually more readily determined and also more accurate. It is the same method which I employed in my studies of the typhoid fever statistics of the city of Chicago in 1892, and I have often employed it in my investigations." What is your opinion as to the validity of using the mortality percentage method in estimating the conditions of typhoid fever in the city of St. Louis?

MR. JEFFRIES: I move to strike out all that part of the question which refers to the statement made by Professor Sedgwick or to the question put to him and all the question with the exception of the latter part which asks the direct question of the witness as to the value he places upon mortality percentages, for the reason that that part of the question which I move to strike out is incompetent, irrelevant and im-
10055 material.

A. I have already indicated my reasons for believing that the mortality percentage method is not a valid method. Uncertain as the population factor may sometimes be, the estimation of the death rate on the basis of population does not involve any such fundamental fallacy as that contained in the mortality percentage method, when owing to the fluctuation in the number of total deaths from year to year it is dealing with two variables and the ratio of deaths from one specific cause to the total number of deaths can not give a true indication of the prevalence of mortality from a specified cause. It is, therefore, my opinion that the mortality percentage method is not a valid one to use in estimating the typhoid conditions in the city of St. Louis.

Q. Is the "mortality percentage" method regarded as on the whole the most accurate among sanitarians and students of vital statistics?

A. In my opinion it is not.

Q. What, in your opinion as a sanitarian and epidemiologist, are the correct and proper methods to be employed in estimating the typhoid conditions in a given city?

A. In my opinion the statistics in the health records should be carefully examined and scrutinized as there are con-
10056 siderable differences in the practice of various health boards and organizations in the matter of reporting deaths under various and varying designations.

The ratios of deaths from a specified cause to the population, or what is known among vital statisticans as the death rate, usually considered on the basis of 1,000, 10,000 or 100,000 population, will then give, with a reasonably accurate estimate of the population, a fairly correct conception of the mortality from year to year and from decade to decade.

ADJOURNED until 1:30 p. m. same day.

10057 1:30 p. m. Tuesday, February 9, 1904. Continuation pursuant to adjournment.

Present, the Commissioner and same counsel representing the respective parties.

PROF. EDWIN O. JORDAN

resumed the stand for further direct examination by Mr. Todd, and testified as follows:

Q. What do you mean by the expression "were to be based on bacteriological and chemical data?"

A. I mean that in my opinion a sanitarian should give such weight to all the evidence that he can obtain from bacteriology, from chemistry and allied science and should even go further and affirm that any information of whatever character, derived from whatever source, that throws light on the questions at issue, should be considered in epidemiological investigations.

Q. What is your opinion as to the value to be placed upon chemical and bacterial analysis of a water course?

A. It is my opinion that such analyses furnish important evidence as to the character of a water, and that while they often supplement and confirm the results of observation, 10058 they also at times reveal conditions that mere ocular inspection or observation would fail to bring to light.

Q. Do chemistry and bacteriology afford any assistance to an epidemiologist or a sanitarian in arriving at a correct judgment to be placed upon the value of a river water, and do they supply facts that are important?

A. In my opinion chemistry and bacteriology often afford very great assistance in arriving at a judgment of the character of a river water. It is sometimes true that chemical and bacteriological data are the only data that one can obtain in regard to the character of a given water and while the inferences from bacterological or chemical data alone are perhaps rarely final, such data are frequently the only available material upon which a judgment can be founded.

In any case an experienced epidemiologist would attempt to secure chemical and bacteriological data regarding the character of a river water as constituting an important element in enabling him to form a judgment of the water.

Q. What light do analyses of a river water shed upon 10059 the problem of self-purification of streams?

A. Here, in particular, analyses offer a material aid in determining the rate and extent of the process of self-purification. Analyses of a river water, polluted at its source, which are made at various points along its course, make it possible to trace the successive changes that take place in the amount and condition of the organic matter in the water, and in the number and kinds of bacteria.

It is my opinion that correct inferences may be drawn regarding the process of self-purification by the study of such analytical data.

Q. Are all these sources of information of which you have spoken about valuable to a sanitarian and epidemiologist?

A. I will reiterate what I have already stated that all sources of information of any kind, tending to shed light on questions in issue, are valuable to sanitarians and epidemiologists and should be investigated and considered.

Q. How is the presence of infectious disease ascertained?

A. In nearly all countries there are regulations requiring physicians to report all cases of certain infectious diseases occurring in their practice, to the health authorities. Some infectious diseases, such as smallpox, are very fully reported in this way, but it is true of many of the infectious diseases, especially the less highly contagious kinds that
10060
such reports to the health authorities are not made uniformly by all physicians.

In most parts of the United States the system of notification of cases of infectious diseases is very imperfect and incomplete. It is perhaps rather the rule than the exception for cases of infectious diseases to be reported promptly and in their full numbers to the health authorities. In too many instances all that the epidemiologist in this country has to depend upon is the mortality returns, the number of deaths recorded by the health authorities rather than the number of cases reported to them. Usually the only clue to the prevalence of typhoid fever in a community during a given period is the number of deaths recorded in the official health reports.

Q. What are the ordinary modes of causation of infectious diseases?

A. The ordinary modes of causation are very different and variable, according to the specific infections. In some cases there is reason for thinking that the infectious matter is air borne, such for example as in the case in tuberculosis and probably in smallpox. In others that the infection is transmitted from one individual to another by more or less
10061
direct contact, as is the case in diphtheria. In still other cases the use of infected drinking water or infected food is the common mode of causation.

Q. What are the chief sources of infection in typhoid fever?

A. The typhoid fever germ usually leaves the body of a patient in the urine or feces. These substances may carry the infection to the sewers, in case proper methods of disinfection are not practiced. The mingling of such infected sewage, containing the discharges from the bodies of typhoid fever patients, with water that is soon afterwards used for drinking purposes is the most common source of infection in typhoid fever, by far the largest number of outbreaks of typhoid fever that have been traced being due to infected drinking water. A considerable number of cases and of epidemics of typhoid fever are however caused in other ways. The milk supply sometimes becomes infected, either directly from a typhoid fever patient or convalescent, or indirectly through the medium of infected water.

Articles of food that are eaten in a raw condition such as oysters, celery and certain fruits may also be the source of infection in this disease.

It may also sometimes happen that the dust from dried
10062 excreta may be blown about and settle upon food and
thus be taken into the alimentary tract.

Insects, too, may play a part in contaminating substances. In the case of physicians and attendants having to do with the treatment of a typhoid fever patient, infection by contact may also occur, and in houses in which there are typhoid fever patients or convalescents, what is known as a secondary infection sometimes results, these cases of secondary infection being due to more or less direct transfer of the discharges of the patient to well persons.

Q. Is it important for the sanitarian and epidemiologist to know the source of infection as well as the results of such infection?

A. It is certainly most important that the source of infection be known since without such information it is impossible to take proper precautionary measures to prevent the spread or recurrence of an epidemic.

Q. Is it a legitimate inference that because typhoid fever increases in a city such increase is due to an increase in the infection of the water supply?

A. By no means, unless other sources of infection are eliminated. An increase of typhoid fever in a city may be due of
course to an increased infection of the public water sup-
10063 ply, but it may also be due to the infection of the milk
supply, to an infection of private wells, to special opportunities for the transmission of the disease by insects or to a change in the character of the population, such as the immigration of a large number of persons of susceptible ages, who had

not previously lived in the city, and acquired a certain degree of immunity.

Q. What other sources of infection are there in a city besides that coming from its water supply?

A. The milk supply; various articles of food; the agency of insects and other factors contribute to an increase in typhoid fever in a given city.

Q. In the case of the city of St. Louis which takes its water supply from the Mississippi River at the chain of rocks, Intake Tower, said river at that point being a mixture of the Missouri, Mississippi and Illinois Rivers—assuming that the reports of the St. Louis Board of Health show an apparent increase of typhoid fever during the years 1900, 1901, 1902, and 1903, as compared with previous years, is there any scientific reason that justifies the conclusion that said apparent increase of typhoid fever in St. Louis is due to infectious matter coming from the sewers of Chicago by way of the drainage canal?

A. Assuming that the reports of the St. Louis Board 10064 of Health show an apparent increase in typhoid fever during the years 1900, 1901, 1902 and 1903, as compared with previous years, it is not in my opinion a justifiable conclusion that said apparent increase of typhoid fever in St. Louis is due to any infectious matter passing into the sewers of Chicago and thence into the Illinois and Mississippi Rivers, by way of the drainage canal. An increase in the infection of the Mississippi River water from points near at hand would seem to me to afford a more satisfactory and scientific explanation of an increase of typhoid fever in St. Louis than the passage of any typhoid bacilli into the intake of the St. Louis waterworks from a point so far removed as Chicago.

Q. What are the instances where the sources of infection that caused epidemics of typhoid fever are known?

A. I have already cited several epidemics in which the evidence seems to me convincing that an infected drinking water was the cause of the outbreak.

Such are the epidemics of typhoid fever at Plymouth, Lowell, Ithaca and Butler, in this country.

An epidemic of typhoid fever traced to infected milk sup-

ply has occurred at Stamford, Conn., and Professor
10065 Sedgwick has described several cases of outbreaks of
typhoid fever in the state of Massachusetts, attributed
to infected milk.

At the time of the Spanish American War in this country outbreaks of typhoid fever among the soldiers in the military camps were traced to infection by flies.

Q. Are there sources of infection which cause typhoid fever epidemics other than drinking water?

A. Yes sir, those that I have already mentioned, namely, milk supply, infected food stuffs, the carriage of the bacilli by flies and perhaps some other agencies.

It has not been recognized until a relatively recent date that the fly can serve as a carrier of the typhoid bacilli. Strong epidemiological evidence for believing that that might be the case was brought out in connection with the occurrence of typhoid fever in the camps at the time of the Spanish American war, as already mentioned.

Since that time it has been definitely proven by Dr. Alice Hamilton, whose results have been printed in an article in the Journal of the American Medical Association for February 28, 1903. Miss Hamilton demonstrated the presence of living typhoid bacilli on the bodies of flies from privies or fences of two
yards, on the walls of houses and in the room of a ty-
10066 phoid patient, and as the result of an extended investi-
gation she concludes that flies played a part in spreading typhoid fever in one section of the city of Chicago in the summer of 1902.

It seems clear from her work that where the discharges from typhoid patients are left exposed in the privy or yards flies may be an important agent in the dissemination of typhoid infection.

Q. What do you mean by intensity of infection as an element to be considered by sanitarians and epidemiologists?

A. The specially severe incidence of disease in one district or in one section of a city might be regarded as a special intensity of infection. If there are 1,000 cases of typhoid fever in one ward in the city as compared with 50 in a neighboring ward, with the same population, the infection might be said to be more intense in one case than in the other.

The word intensity might be used, too, I suppose, to indicate severity of individual cases of disease. If among 1,000 cases of typhoid fever in one ward 200 died while in a neighboring ward with the same number of cases only 50 died, the intensity of infection might be said to be greater in the former case than in the latter.

Q. What evidence have you that the nearer the sources 10067 of infection the more severe the incidence of the disease?

A. It has been observed that where a community is served by an infected water supply there are often fewer cases of typhoid fever in the periphery of the town at a distance from the central source, than they are close to the point where the water is pumped into the mains. In other words, the greater the distance from the source of infection the less the intensity of the disease. The nearer the source of infection the more severe the incidence.

Q. Do you know of any facts or observations that justify the conclusion that the more remote the source of infection the less severe the disease?

A. The observations that I have just alluded to are observations of this character and indicate that the more remote the source of infection the less severe is the incidence of disease.

Q. Is there such a thing as decrease in the virulence of a typhoid fever germ?

A. It is probable that there is a decrease in virulence of a typhoid fever bacillus after its discharge from the human body although the evidence on this hand is scanty and not altogether satisfactory. Such evidence as there is, however, indi-
10068 cates that some decline in the virulence of a typhoid bacillus through a prolonged sojourn in water probably does occur.

Hankin (Centralbl f. Bakt. 1899, 26, p. 544) mentions that on a number of occasions he has found typhoid bacilli in waters at a time when these waters were being used for drinking purposes and that in several such instances no cases of fever developed among the users of such waters.

Indeed, he specifically takes the ground that "My finding typhoid microbes in a water supply gives no proof microbes were then present in a condition in which they could produce infection."

Remlinger and Schneider (Ann. de L'Inst. Pasteur, 1897, II, p. 55).

"Also encountered typhoid bacilli in waters that were not giving rise to fever and that water designated by them as being very pure."

Kubler and Neufeld (Zeitscher f. Hyg., 1899, 31 p. 133).

state that the typhoid bacillus that were first isolated by them from well water would kill a guinea pig in the dose of one-fifth of a loop, whereas a culture isolated later from
10069 the water of the same well did not prove fatal to a guinea pig in a dose five times as great.

There thus seems to be good reason for believing that by prolonged aquatic life typhoid bacilli are rendered innocuous or at least less virulent even where they are able to survive at all. The evidence then as to the decrease in virulence of a typhoid fever germ indicates, such as it is, that the longer a typhoid bacillus remains in water the less likely it is to cause disease.

Q. What do you mean by the decrease in virulence of a typhoid fever germ?

A. By decrease in virulence of a typhoid fever germ, I mean a diminution in its power to invade the human body and bring about pathological conditions.

Q. What is your opinion as to the relative virulence of a typhoid bacillus coming from a remote as compared with a nearer source?

A. It is my opinion, based upon such evidence as exists as to the diminution in virulence of a typhoid bacillus, that the longer such a bacillus sojourns in the water of a lake or river, the less likely it is to cause disease. It follows, consequently, that a typhoid bacillus after making a long journey by
10070 water will be less virulent than after a short journey.

Q. Will you distinguish between the effect of an urban and rural population upon a water shed?

A. I take the question to imply that the sewage and drainage from such urban and rural communities are discharged without purification or special treatment into the streams upon such water shed. It is now true that most urban communities are provided with sewers and it is also true that such sewage often passes directly into the nearest watercourse. The amount of pollution added directly to a river by an urban community is therefore considerable.

In the case of a rural community or of isolated dwellings or scattered farm houses the waste matters due to human life and habitation are not added as a rule so directly to the stream, although, as is well known, in most parts of this country it is a common custom for the outhouses and privy vaults to be located on or near the banks of small brooks or rivulets.

On the whole, however, the total amount of organic matter added to a water course by an urban community 10071 provided with sewers is greater per capita than the amount of similar organic matters added by a rural population of the same dimensions.

Q. Is typhoid fever more prevalent in urban than in rural communities?

A. No sir—just the reverse is true. Typhoid fever is a rural rather than an urban disease.

For example the death rate from typhoid fever in the thinly populated "Adirondacks and Northern" district of New York state in 1900 was 3.9 per 10,000 as compared with 2.0 in the so-called maritime district, including New York and the population thickly settled along the seaboard. This is only one of many instances that might be given as to the greater prevalence of typhoid fever in the country than in the city.

As confirmation of this statement I may quote from an article on typhoid fever in the Journal of the American Medical Association for January 9, 1904, by Dr. John S. Fulton of Baltimore.

According to the figures given by this authority, derived from the 12th census of the United States, typhoid fever 10072 is conspicuously a rural disease. He says "When we examine the rank of typhoid fever among all the causes of death we find that rural typhoid fever is credited with 62 in every 1,000 deaths as against 38 per 1,000 from urban typhoid." This writer gives elaborate diagrams and tables which bring out with great clearness the fact that typhoid fever at the present time in the United States is a rural rather than an urban disease.

Q. Is the danger from a rural population to be given slight consideration by a sanitarian or an epidemiologist?

A. It is my opinion that the danger from a rural population can by no means be ignored by any sanitarian or epidemiologist who wishes to take into account all data bearing upon questions of the spread and transmission of infection.

Q. Is the rural population on the water shed an important factor to be considered in passing upon a water supply of a city using river water for domestic and drinking purposes?

A. In my opinion it is a very important factor since serious infection of a water course may be due to rural infection. I am aware that the significance of rural population in this connection is not always assigned the importance which
10073 in my opinion it deserves.

Q. Professor Sedgwick, in his testimony (page 3,620 of my transcript of the record), stated in reply to the question: "Is it not a fact in sanitary science that the pollution of rivers by what we term the rural population is a very large factor in the consideration of the amount and the degree and kind of pollution," answered, "of pollution, yes sir." Question: "But scientifically considering infection you do not take it into account?" answer, "Not so much because the rural infection to begin with is well known and in the second place, owing to the time factor which is apt to come in, in the partial purification of the pollution the infectious matter may be destroyed." Is it a fact that the infection in the rural population is less common?

A. As I have just stated, typhoid fever is more prevalent in rural than in urban districts. So far from the disease being less common in a rural population the facts, in my opinion, show that it is more common.

MR. JEFFRIES: I move to strike the answer out because it is contained in a previous answer, and the question be-
10074 cause it is repetition, no new facts being brought out either by the question or the answer.

Q. Does the time factor mentioned by Professor Sedgwick really play an important part in preventing rural infection of water courses?

A. It is of course well recognized that in rural communities a longer period may elapse after the discharge of typhoid bacilli from the bodies of typhoid patients before the bacilli enter water courses, than is the case with such discharges in an urban community furnished with a sewage system.

It is also well known that typhoid bacilli in the infections or infectious discharges from the body of typhoid patients, when emptied into a loosely constructed privy vault or outhouse may retain their vitality and virulence for a long period. Such was the case in the Plymouth epidemic already cited.

Typhoid bacilli have been known to retain their vitality for upwards of five months in the contents of privy vaults. It is evident that if the contents of such vaults or outhouses be washed down into a stream by heavy rains or melting snows, or if the contents of said vaults be spread as manure
10075 upon fields near the banks of a river or other stream, the bacilli may find their way into the water course.

Despite the fact, therefore, that a long time elapses after the discharge from the body of the patient, and before such germs find their way into the water, the infectious matter may not be destroyed, owing to the conditions under which it is stored.

The time factor, therefore, would be of less significance in this connection than where bacilli were discharged directly into the stream itself.

Q. Do you know of any important typhoid epidemics in which infection has come from the rural population?

A. The most extensive localized epidemics of typhoid fever in this country, namely those at Plymouth, Pa., Ithaca, N. Y., and Butler, Pa., have been caused by infection from a rural population.

The epidemic at Lowell, Mass., was also due to the infection of the Merrimac River by isloated cases of typhoid fever and not from a population provided with sewers.

Q. Are there any reasons why infection from the rural
10076 population is to be specially feared?

A. It seems to me that there are at least two reasons why infection of a water course by a rural population is especially to be feared.

Q. What are those reasons?

A. The first of these is that, on the whole, disinfection of the dejecta and urine is less carefully and thoroughly carried out in rural communities than in urban, so that in a given number of cases of typhoid fever a larger proportion will be improperly cared for in rural communities than in cities.

In the second place, the storing up or accumulation of infectious material from typhoid cases may result in a very heavy infection of a water course, since the discharges that have collected during the whole course of a case of typhoid fever may be washed, all at once, by a heavy rain into a watercourse.

Still another reason and one that I believe to be very important is that when typhoid bacilli are added to a stream in the sewage of an urban community, they are accompanied by a large amount of organic matter and a large number of saprophytic bacteria.

10077 In rural infection on the other hand, the bacilli from a single case of typhoid fever may pass into a stream unaccompanied by any considerable amount of organic matter. The dilution with pure water of this relatively large number of bacilli and their mingling with the waters of a large stream constitute a peculiarly dangerous kind of infection. The competition of the sewage bacteria in such a case is not nearly so great as in the case of typhoid bacilli passing into the sewers of a large city.

It has been shown previously that typhoid bacilli will live longer in relatively pure water in the presence of a relatively small amount of organic matter than in a polluted water, charged with the sewage of a great city.

For these reasons, therefore, it is my judgment that the infection from a rural population should not only not be ignored but should be especially feared.

Q. What do you mean by character of diseases as an element to be considered by sanitarians and epidemiologists?

A. I mean by that that the vital statistics, the reports of morbidity and mortality should be examined with a view to determining the class and nature of the disease as disclosed by an analysis of the alleged causes of death as reported in 10078 the official publications. The discrepancies in nomenclature and the varying practice of the custodians of public health records in the various parts of the country render such examination necessary if a correct idea is to be obtained regarding the actual character of the disease present or rife in a given community.

Q. Have you examined the typhoid mortality statistics of the city of St. Louis as evidenced by the reports of the Board of Health of the city of St. Louis?

A. I have.

Q. Have you examined the typhoid mortality statistics of the city of Chicago as evidenced by the reports of the Board of Health of the city of Chicago?

A. I have.

Q. Have you prepared a table of typhoid deaths based upon those reports?

A. Yes sir, I have a table of the deaths reported from typhoid fever in St. Louis by months from January, 1890, to December, 1903, inclusive, and I have a similar table for Chicago for exactly the same period.

Q. Will you produce and read the mortality typhoid statistics of the city of St. Louis and the city of Chicago 10079 as compiled by you from the Board of Health reports of those two cities, covering said periods?

A. They are as follows:

10080

TYPHOID FEVER, ST. LOUIS.

10084 Q. What relation do the monthly deaths from typhoid in Chicago bear to those in the city of St. Louis the period from 1890 to 1903, inclusive?

A. From these tables I am unable to discover any relation between the monthly deaths from typhoid fever in Chicago and those in St. Louis.

I have compiled from these tables a statement showing those months of maximum typhoid fever in Chicago and St. Louis and those showing the minimum deaths from typhoid fever in these two cities.

The month showing the largest number of deaths in Chicago precedes the maximum in St. Louis by 11 months in one year (1892),
by 8 months in one year (1903),
by 6 months in one year (1891),
by 5 months in two years (1896 and 1898),
by 3 months in one year (1899),
by 2 months in one year (1902).

The Chicago maximum coincides with the St. Louis maximum in five years, namely: 1893, 1895, 1896, 1897 and 1900.

The minimum typhoid fever in Chicago precedes the
10085 minimum in St. Louis in six years, namely, 1891, 1893,
1898, 1900, 1902. The Chicago minimum coincides with
St. Louis minimum in 2 years, 1892 and 1890, and follows the St. Louis minimum in 7 years, 1890, 1894, 1895, 1896, 1897, 1901 and 1903.

Q. Have you made a study of the typhoid death statistics of the City of St. Louis and Chicago covering that period?

A. Yes sir, I have examined these very carefully and the results are set forth in the tables as just recorded.

Q. Is an increase in the death rate from typhoid fever in St. Louis preceded by a corresponding increase in the death rate from typhoid fever in Chicago?

A. It is not.

Q. Is a decrease in the death rate from typhoid fever in Chicago followed by a decrease in the death rate from typhoid fever in St. Louis?

A. I am unable to discover any relation between the monthly deaths from typhoid fever in Chicago and those in St. Louis.

A decrease in the number in Chicago is not followed by a decrease in the number in St. Louis, nor is an increase in the deaths in St. Louis preceded by a corresponding increase in the deaths in Chicago.

Q. If the typhoid fever in St. Louis, for the period from
10086 1890 to 1903, inclusive, was caused by infection coming
from the city of Chicago, would not some relation exist between typhoid conditions in Chicago and the typhoid conditions in St. Louis?

A. I should certainly expect to find some relation obtaining between the prevalence of this disease in Chicago and that in St. Louis.

I should anticipate that in general if the typhoid fever conditions in St. Louis were dependent upon those in Chicago that a large number of deaths from typhoid fever in the latter city would be followed within three or four months by an increase in the number of typhoid deaths in St. Louis.

No such relation appears in the monthly records of typhoid fever of these two cities as tabulated.

It is therefore my judgment that typhoid fever conditions in St. Louis are unaffected by a large amount or a small amount of typhoid fever in Chicago.

ADJOURNED until 10:00 a. m., February 10, 1904.

10087 10:00 a. m., Wednesday, February 10, 1904. Continua-
tion pursuant to adjournment.

Present, the Commissioner and same counsel representing the respective parties.

PROF. EDWIN O. JORDAN

resumed the stand for further direct examination by Mr. Todd and testified as follows:

Q. What relation do flood waters in the Illinois River bear to the increase or decrease of typhoid fever deaths in the city of St. Louis?

A. I have prepared a table showing the water gauge readings obtained by the United States engineer at the Kampsville Lock, by months, for the years 1899, 1900, 1901 and 1902. These are the means of tri-daily readings. The readings are referred to the lower miter sill, or 7 feet below low water.

I find on comparing these readings of the heights of water in the Illinois River at the Kampsville Lock, that high water occurred in March, 1899, and low water in September, 1899. The maximum typhoid fever in St. Louis in that year occurred in the month of November and the minimum typhoid
10088 fever in the month of May.

In 1900 the high water period was again in the month of March and the lowest water recorded in January. The maximum typhoid fever in 1900 was in the month of October and the minimum in the months of April and May. In 1901 the maximum height of water occurred in the month of April and the low water period in October. The maximum typhoid fever in St. Louis occurred in the month of October and the minimum in the month of April.

In 1902 the maximum high water occurred in the month of July and the minimum in the month of January. The maximum typhoid fever in St. Louis occurred in the month of October and the minimum in the month of June.

A very interesting comparison may be made between the months of July, August, September, October and November, 1901 and 1902. The water in the Illinois River averaged nearly twice as high in 1902 as in 1901 and yet the typhoid fever at St. Louis was almost exactly the same in the latter part of those years as is shown by reference to the tabulated table of monthly deaths.

Q. When there is low water in the Illinois River what
10089 effect does that stage of water have upon the increase or decrease of typhoid fever in St. Louis?

A. From an examination of the tables just referred to I am unable to discover any connection between the stage of low water as disclosed in the gauge readings at Kampsville and a large amount or small amount of typhoid fever in St. Louis.

In the four years for which record is at hand, absolutely no relation exists between low water in the Illinois River as shown in the gauge readings at Kampsville and an increase or decrease in the typhoid mortality in the city of St. Louis.

Q. Is a high death rate from typhoid fever in Chicago, during cold weather, followed by correspondingly high death rate from typhoid fever in the city of St. Louis, allowing for the period of incubation and distance of flow between Chicago and St. Louis?

A. From an examination of the monthly deaths reported from typhoid fever in St. Louis, I am unable to discover any such relation between a high death rate from typhoid fever in Chicago in the winter months and the typhoid mortality in St. Louis, two or three months later, when allowance is made for the periods of incubation and time of flow between Chicago and St. Louis.

10090 Thus, in December, 1900, the number of deaths reported from typhoid fever in the city of Chicago was the largest reported for any month in that year. In the early months of 1900 in St. Louis no marked increase of deaths appears as a consequence of the large number of deaths in Chicago.

Again, in 1902, the number of deaths from typhoid fever for Chicago in December and also in January, 1903, was very extensive, but the number of deaths in St. Louis in March, April and May of 1903, was not materially in excess of those in the preceding year when the number of typhoid deaths in Chicago for the corresponding months of January and December had not been one-fourth as great.

Q. From a careful study of the typhoid death rate in St. Louis and Chicago, covering the period from 1890 to 1903, inclusive, taking into consideration the seasons of the year and the stages of the water in the Illinois River, is there, in your opinion, any relation existing between the typhoid conditions in St. Louis as evidenced by its mortality statistics and the typhoid conditions in Chicago, as they exist, as evidenced by the mortality statistics of Chicago, showing that the typhoid condition in St. Louis during this period is due as a whole or in part to infection coming from the city of Chicago?

10091 A. From an examination of the monthly deaths reported from typhoid fever in Chicago and St. Louis between 1890 and 1903, inclusive, I am unable to discover any dependence of the mortality in St. Louis upon that in Chicago, as respects extent of mortality, season of year or stages of water in the Illinois River.

Q. Have you made a special study of the so-called germ diseases?

A. Yes sir, in connection with my work in bacteriology I have had to study a number of the so-called germ diseases with considerable care.

Q. Do these diseases caused by germs come within the scope of your study?

A. Yes sir, it is generally conceived that the scope of bacteriology today includes the various diseases due to germs of various kinds, to those closely related to bacteria as well as to bacteria themselves. I refer especially to the so-called protozoan diseases of which malaria is a type. The malaria germ is not a bacterium properly speaking, but a protozoan. Malaria is, however, one of the germ diseases and is studied and investigated by bacteriologists.

Q. Will you distinguish between a protozoan and a bacterium?

A. A protozoan is a one-celled animal; a bacterium a one-celled plant.

10092 The protozoa are of a more complicated sturcture than the bacteria and possess as a rule more intricate life histories. Protozoa are the lowest members of the animal series as the bacteria are the lowest plants known.

Q. What studies have you made upon typhoid fever and malaria fever from the standpoint of a bacteriologist?

A. I have examined the organisms of these diseases and have made blood examinations from cases of typhoid fever and malaria and have examined the literature with reference to the geographical distribution, fatality and general character of these diseases.

Q. In connection with such study as you have detailed, does that lead you into the question of the proper diagnosis of the fevers, the kinds of typhoid and malaria?

A. Yes sir, that has become a very important question in bacteriological laboratories in the last few years. It is now generally recognized that a very important and perhaps the most important means of distinguishing between typhoid fever and malaria is by examinations made in the laboratory.

Q. Have you had any experience with the diagnosis of these fevers?

Yes sir, I have examined and caused to be examined
10093 blood coming from patients suffering from these diseases.

Q. Have you studied these questions sufficiently to give an expert opinion upon them?

A. I think that I have.

Q. What is typhoid fever and its clinical diagnosis?

A. The symptoms of the disease known as typhoid fever are quite various, but the disease is characterized ordinarily by certain well marked peculiarities, such as the temperature curve with its gradual step-like ascent, until the height of the fever is reached, and then its gradual step-like decline. The onset of typhoid fever is often marked by a severe headache, although this symptom may be absent. There is often abdominal pain and tenderness. In a considerable proportion of cases, over 70 per cent., I believe, rose-spots appear on the abdomen. These spots are due to typhoid bacilli in the skin where the spots become reddened. This is a specific eruption due to typhoid bacilli in those cases.

Epitaxis is not an uncommon symptom in this disease. In most cases of typhoid fever a few days after the onset of the
attack an examination of the blood by what is known as
10094 the Widal test affords a highly characteristic mark of
the disease and is one of the most important diagnostic features. The blood of patients suffering from genuine typhoid fever responds positively to this test while the blood of well persons or persons suffering from other diseases than typhoid fever give as a rule negative results.

Q. What is malarial fever and its clinical diagnosis?

A. There are three well recognized types of malarial fever, due to three different kinds of parasites. These different types of fever are characterized by a difference in the periodicity of the well known malarial paroxysm. In the tertian type of malarial fever the parasite completes the cycle of its development every 48 hours. The onset of the paroxysm coincide with the sporulation of the parasite and the disintegration of the blood corpuscles that accompanies this process. The tertian form of malarial fever is much more common in the temperate zone than either of the other phases. It is rarely, if ever fatal in its uncomplicated form.

The quartan malarial fever is caused by a parasite very similar to the tertian parasite, but completing its life cycle in 72 hours instead of 48. The malarial paroxysm occurs every third day instead of every other day, as is the case in
10095 the tertiary fever.

Tropical malarial fever is caused by a parasite with a somewhat irregular cycle of development; the parasite of the tropical fever is not so commonly found in the circulating blood as the others, but carries out a large part of its life history in the internal organs, such as the spleen. This is the most serious of the three types of malarial fever. These parasites, the tertian, the quartan and the tropical parasite can be recognized by a blood examination. The parasites, in each case, invade the red blood corpuscles and pass through the various phases of their development ensconced in the body of the red blood corpuscles.

Q. What is intermittent fever and its diagnosis?

A. The term intermittent fever refers to that type of fever in which the temperature after being high for some time is intermitting, and the temperature of the individual returns completely to the normal. The term is loosely used but is applied often times to various forms of malaria.

Q. Is it a distinct type of fever?

A. It is not.

Q. What is remittent fever and its clinical diagnosis?

10096 A. The distinction between remittent and intermittent fever lies in the fact that the temperature does not return completely to normal in the remittent, but rises and falls.

Q. Is remittent fever a distinct type of disease?

A. It is not. The symptom of remittency may characterize various pathological conditions.

Q. What is typho-malaria fever and its clinical diagnosis?

A. The term typho-malaria fever as ordinarly applied in this country is used for fevers which may be either typhoid or malaria. Most of the cases of so-called typho-malaria are really cases of typhoid fever. It may rarely happen that a mixed infection occurs, that an individual is infected both with the bacilli of typhoid fever and with some one of the malarial parasites, but these cases are so rare as to rank as medical curiosities, and have no far-reaching significance. Typho-malaria fever is not a distinct entity.

Q. What is congestive fever and its clinical diagnosis?

A. The term congestive fever is a vague term, comprising no definitely recognized type of disease. The symptom of congestion of various internal organs such as the liver is what has perhaps given rise to the use of this term.

10097 No such disease as congestive fever is recognized by the best physicians at the present day.

Q. What is simple continued fever and its clinical diagnosis?

A. The term simple continued fever is an old term in medicine which owes its origin to a period when methods of diagnosing diseases were not so far advanced as at present. As the name implies, it refers to a type of fever in which the temperature remains high for quite a long period. Most of the cases that would be likely to be reported as cases of simple continued fever at the present time are simply cases of mild typhoid fever.

Q. Are intermittent fever, remittent fever, typho-malaria fever, congestive fever and simple continued fever distinct types of fevers and so recognized by bacteriologists and clinicians?

A. Most of the affections designated by these different names are either typhoid fever or malaria, and these terms, mentioned in your question, are not generally employed at the present time as representing different and specific types of disease.

10098 Q. What epidemiological and sanitary significance are attached by statisticians to these fevers as above described, when they appear in vital statistics?

A. It is generally considered that these designations relate in almost every instance to cases of typhoid fever and that they should be so regarded.

It is the general opinion among statisticians that the deaths so classed should be transferred bodily to the column of deaths from typhoid fever since they are practically in all cases death from typhoid fever and not deaths from malaria. Malaria in fact, as it occurs in temperate countries is rarely fatal.

Professor William Osler of Johns Hopkins University, in his article on malaria fever in Allbutt's System of Medicine, Vol. III, p. 738, states:

"Unfortunately for many years and in many regions practitioners have been in the habit of labeling as malaria every instance of obscure disease in which they could not make a diagnosis; so that the vital statistics are falsified in a remarkable manner. In the United States Census Report for 1890, which covers the six preceding years, the deaths from 10099 malarial fever in New York and in Brooklyn were more numerous than from typhoid fever. In both these cities it is notorious that a death from true malaria is a great rarity, not more than three or four cases occurring each year in the entire hospital practice of the city of New York."

"In the regular forms of malarial fever the death rate is very slight, and results usually from complications, such as acute nephritis."

In the testimony of Dr. William C. Woodward, who has already testified in this case, page 4602, I find the question:

"In this table marked Exhibit 74, you have what is known as typhoid malaria and typhoid fever. What is the difference between typhoid fever and typhoid malaria"? The answer: "I regard a case of typho-malaria fever as a case of typhoid fever, in which the physician has made a mistake at the beginning and called it malarial fever, and he seeks the best way to get out of the hole. We classify them separately because some people regard them as different diseases, and we furnish our statistics to people and let them use them as they see fit, but I have expressed my opinion."

"There is a very marked distinction between malarial 10100 fever and the other diseases, unless you regard the typho-malarial fever as typhoid fever. When it comes to typhoid malaria and typhoid fever, the best authorities today, I believe, regard them as the same disease."

In a recent article by Dr. John S. Fulton, Health Officer of Baltimore, Maryland, entitled "Typhoid Fever," and appearing in the Journal of the American Medical Association, for January 9, 1904, this matter of the relation between typhoid fever and malaria is exhaustively discussed with a very full statistical presentation. On page 74 of this article is given a series of charts, showing the typhoid mortality and the reputed malaria mortality in different sections of the United States. These charts show that the malaria curve below the line reflects the typhoid curve above as faithfully as the shores are reflected by the surface of a lake, the seasonal apex of the groups corresponding.

Dr. Fulton states his own opinion as follows:

"My personal belief is that fatal malaria intoxication does not happen to one citizen a year in Maryland, though malaria is in some parts of the state a considerable cause of disability."

Then again: "Of all the mortality charged in the South to malaria, death perhaps is due to typhoid fever. The United
States Army experience would indicate that not more
10101 than half is due in fact to typhoid, and certainly more
than 50 per cent. of the mortality so charged is not due to malaria. In the North a much larger part, probably two-thirds of the reputed malarial mortality, represents unrecognized typhoid."

Outside of certain well known areas malaria does not kill citizens of the United States, and within those areas, where malaria is a cause of grave sickness, its right to be considered an important cause of death has not been subjected to the rigid scrutiny which its apparent importance demands."

"Speaking for that part of the United States that I know best, I can say that the terms "malarial" and "typho-malarial" express no definite belief as to the cause or character of a disease,
but are applied to fevers of inderterminate nature."
10102 It is my opinion that these statements represent cor-
rectly the prevailing judgment regarding these designations of intermittent fever, etc., used in mortality records. The great majority of the deaths so reported are due to typhoid fever.

Q. Mr. William C. Woodward, whom you quoted, is the Health Officer of the District of Columbia is he not?

A. I believe that he is.

Q. Does the number of deaths reported as occurring from typhoid fever in the City of St. Louis, according to the reports of the St. Louis Health Department represent, in your opinion, the total number of typhoid deaths actually occurring in that city for the period from 1890 to 1903, inclusive?

A. They certainly do not.

Q. What reasons have you for stating that they do not?

A. I find in the records of the Health Department of the City of St. Louis a very considerable number of deaths under the heading remittent, intermittent, typho-malarial, congestive and simple continued fevers. I have already given what seems to me adequate reasons for believing that the majority of these, if not indeed all of them, were deaths from genuine typhoid fever and properly should be so classed.

10103 Q. To what do you attribute the failure of these statistics to properly disclose the number of typhoid fever deaths occurring in the City of St. Louis?

A. Since there is, in my opinion, no question that a number of deaths reported under the head remittent, intermittent, typho-malarial, congestive and simple continued fevers were undoubtedly deaths from typhoid fever and since there is no precise method of determining just what proportion of these deaths were actually deaths from typhoid fever, it is certainly difficult, if not impossible, to determine how many typhoid fever deaths actually occurred in St. Louis during a given year, particularly since the number of deaths recorded under the heading remittent fever, etc., is so very large in St. Louis.

Since there is no reason to suppose that these figures do not correctly represent the reports received from the physicians of St. Louis, I see no escape from the conclusion that the value of these statistics to properly disclose the number of typhoid fever deaths occuring in St. Louis was due to an improper diagnosis.

Q. Why is it that doctors will apply the terms remittent, intermittent, typho malarial, congestive and simple continued to fevers that are recognized as being typhoid or malaria?

10104 A. These terms that you mentioned have the weight of traditional use behind them. Furthermore it is only in relatively recent years that the sure distinction and differentiation of typhoid and malarial fevers has become possible, through the application of laboratory methods. Many of the physicians who received their medical education before these laboratory methods were in vogue do not habitaually employ such methods in their practice, and without these modern methods, on the basis of clinical symptoms alone, it is often difficult and indeed well nigh impossible to differentiate obscure and indefinite types of fever.

Q. Do you know of any city in the country where the death rate from malaria alone is as high as in the City of St. Louis, as evidenced by the Board of Health reports of that city?

A. No sir, I do not. In my opinion no city in the United States has as large a death rate from genuine malaria as would be indicated by the official records of St. Louis, assuming that all deaths reported under this head of remittent, intermittent fever, etc., were deaths from malaria.

10105 What do the malaria statistics show in cities where careful attention has been paid to malaria fevers?

A. In the city of Baltimore where particular attention has been paid to the study of malaria and typhoid fever and their diagnosis, at the Johns Hopkins University Medical School, the effect of such study is shown in the relatively small number of deaths reported from malarial and typhoid malarial fevers.

I may say that it is the practice in that city to class the deaths reported from typho-malarial with the deaths from typhoid fever rather than with malarial. This seems to be an indication that the health authorities of that city are convinced that the deaths reported by physicians as occuring from typho malarial are in reality cases of typhoid fever.

Q. Is it generally recognized by sanitarians and epidemiologists that classifying typhoid fever in one column and remittent, intermittent, typho malaria, congestive and simple continued fevers in another column in board of health reports is an improper classification from a scientific standpoint of view, as affording a true indication of the prevalence of typhoid fever and malaria?

A. In my opinion the classification is so recognized.

10106 A truer indication of typhoid fever mortality would be obtained by adding the deaths reported under the miscellaneous headings to the deaths reported as occurring from typhoid fever. This confusion of the records of vital statistics is, of course, especially liable to occur in those districts where malaria is prevalent and where a faulty diagnosis on the part of the attending physician is more liable to occur.

Q. Have you compiled from the board of health reports of the City of St. Louis, a table showing the typhoid deaths by each month from 1895 to 1903, inclusive, with a table for the same period, with the fevers indicated at the heading, remittent, intermittent, typho malarial, congestive and simple continued fevers?

A. I have.

Q. Will you produce and read into the evidence, the compilations which you have made?

A. It is as follows:

10107

ST. LOUIS.

A—Typhoid Fever.

B—Remittent, Intermittent, Typho-malarial, Congestive and simple continued fever.

10109 Q. Will you state what this table shows?

A. This table shows the deaths in St. Louis by months from January, 1895, to December, 1903, inclusive, recorded under the headings A typhoid fever, B, remittent, intermittent, typho-malarial, congestive and simple continued fevers.

The table shows a close parallel between the number of deaths reported from these two causes. In the months of July, August, September and October the number of deaths reported under both of these headings is high, while in the months of April and May it is on the whole low.

An interesting change is noted in the latter part of this table. For the first five years of the table the number of deaths under the heading B (remittent fever, etc.), was greater than the number of deaths under the heading A (typhoid fever). Beginning with 1901 the reverse is true. The number of deaths reported under the heading typhoid fever becomes greater than the number reported under the heading remittent fever. To take for example the month of September:

	A (typhoid fever)	B (remittent fever etc.)
1895	9	32
1896	13	27
1897	17	31
1898	14	18
1899	16	28
1900	13	20
1901	24	9
1902	21	16
1903	42	17

10110 Inspection of these figures shows that in the last four years there has been a transfer from the column B, that of remittent fever, etc., to the column A, that of typhoid fever, the effect being to diminish the number of deaths reported as remittent fever, etc., and increase those reported as typhoid fever.

Q. Have you prepared a table from the board of health reports of the City of St. Louis for the years 1890 to 1903, inclusive, showing the number of deaths reported in the typhoid column the number of deaths in the remittent, intermittent, typho-malarial, congestive and simple continued fever column, and the added totals of these two columns for the period above mentioned?

A. I have.

Q. By whom was the table that you have already read in evidence and the one that you now have prepared, and from what source was the information taken that is contained in the tables?

A. These tables were prepared by me personally and the information upon which they are based was obtained 10111 from the official reports of the health department of the City of St. Louis.

Q. Will you read the table last described by you in evidence?

A. It is as follows:

10112 ST. LOUIS. Population 1900, 575,238

Year	Typpus Typhoid Fever	Reported Deaths from Remittent, Intermittent, Typho-malarial Conjestive and simple Continued Fevers.	Total
1890	140	226	361
1891	165	216	381
1892	441	326	767
1893	215	284	499
1894	171	179	350
1895	107	155	262
1896	106	177	283
1897	125	172	297
1898	95	134	229
1899	131	148	279
1900	168	112	280
1901	198	80	278
1902	222	102	324
1903	288	91	379

Q. State what the table you have just read in evidence 10113 shows?

A. This table shows a similar condition to that evidenced in the table of monthly tables just produced. The total number of deaths per year reported under the heading typhoid fever, and under the heading remittent fever, etc., are given in this table.

They show that a much larger proportion of deaths is recorded under the heading remittent fever, etc., before the year 1900 than since that year.

They also show that whereas the number of deaths reported from typhoid fever was generally less during the first 10 years of this period than the number of deaths reported from remittent fever, etc., during the last four years, the case has been just reversed. It is evident that there has been some cause or that there have been some causes at work tending to produce a more accurate diagonsis on the part of the physicians and that a larger number of cases of true typhoid fever have been recognized as such during the latter period than during the earlier one.

Q. Professor Teichmann testified (page 2336 of my transcript of the record) that two circular letters "one issued 10114 in the fall of 1900 and another one issued in the fall of 1901" were "issued by the Health Commissioner of St. Louis, calling the attention of physicians to the fact that the law required them to report all cases of typhoid and all deaths from typhoid" and at the time that letter was sent out the question of opening the drainage canal was being agitated in the public press of St. Louis and there was considerable discussion" and an investigation was going on at that time of the analyses of the samples, etc.," and that attracted considerable attention. From your examination of the statistics of St. Louis for the years 1900, 1901 and 1902, as compared with previous years, does the effect of such a letter, as testified to having been sent to the doctors of St. Louis by the health department of St. Louis, manifest itself in the statistics?

Mr. Jeffries: Objected to for the reason that it is for the court to determine from all the evidence whether any effect whatever was produced by the issuance of the letter as testified to by Professor Teichmann, and not for this witness to draw conclusions therefrom, the question not eliciting expert analysis or testimony.

10115 A. It certainly seems reasonable to suppose that such a letter as that described in your question as having been sent to the physicians of St. Louis would have some effect upon their scrutiny of cases of fever and that it might cause them to pay closer attention to diagnosis and perhaps apply some of the modern methods of differentiating typhoid fever from conditions for which it might be mistaken.

It is certainly in my opinion a significant fact that since 1900 there has been this decided change in the mode of reporting deaths.

Mr. Jeffries: I move to strike out the answer for the reason stated in the question, and for the further reason that the answer is all together argumentative and it is not for this witness to argue this case.

Adjourned until 2:00 P. M same day.

2:00 P. M., Wednesday, February 10, 1904.

10116 Continuation pursuant to adjournment.

Present, the Commissioner and same counsel representing the respective parties.

PROF. EDWIN O. JORDAN

resumed the stand for further direct examination by Mr. Todd, and testified as follows:

Q. In what way does the effect of such letters appear on the statistics?

MR. JEFFRIES: Objected to for the same reason as contained in my objection to the last preceding question.

A. Beginning with the year 1900 the proportion of deaths from typhoid fever is much greater as compared with the deaths from intermittent fever than in the preceding decade. This is just the effect that would be expected if the attention of the physicians had been specially directed to the diagonsis and differentiation of typhoid fever in its various forms, including obscure and mild cases.

For the three years, 1899, 1900 and 1901, the total number
of deaths reported from "typhoid fever," and "remittent
10117 fever, intermittent fever," etc., is almost precisely the
same, but the proportion reported from typhoid fever
alone in 1900 and 1901 is much greater than in 1899.

Q. From your examination of the typhoid and typho-malarial group (meaning to include in the latter those deaths reported under the head of remittent, intermittent, typho malarial, congestive and simple continued fevers), what is your opinion as to whether these two tables taken separately correctly show the typhoid condition in the City of St. Louis for the period mentioned?

A. It is my opinion that considering the number of deaths reported separately under the heading typhoid fever, that the total number of such deaths and the average number is not correctly represented by the tables reported under this head alone.

Q. Upon what do you base your opinion that they do not correctly show the typhoid conditions in the City of St. Louis, taking them separately?

A. I base my opinion upon all the facts that are known

concerning the sources of error in the collection of vital
10118 statistics, the possibility of error in diagonsis in this
group; the improvements in methods of diagnosis during
the last few years, and the attention that has recently been
specially focused upon this group of diseases.

There is every reason to suppose that during the first five years covered by these tables a larger proportion of the deaths recorded under the heading "intermittent fever, etc." were genuine typhoid fever than in the latter period owing chiefly to the progress that has been made in the methods of diagnosis.

Q. From your knowledge of the classes of fevers mentioned in these two columns of vital statistics, taken from the board of health reports of the City of St. Louis, how should they be treated by an epidemiologist and sanitarian in order to arrive at the true condition of typhoid fever in the city of St. Louis?

A. That is a difficult question to answer owing to the fact that during the latter portion of the period covered the conditions of record and diagnosis have not been strictly comparable with those in the early portion of this period.

One way of attempting to arrive at the true typhoid mor-
10119 tality in the city of St. Louis during the period indicated
would be by assuming that all the deaths recorded under
the heading "remittent fever, etc." were actually cases of typhoid fever and should be added to those in the column of typhoid fever proper.

Another method would be to assume that a certain proportion of the deaths reported from remittent fever. etc., say 50 per cent. were deaths from genuine typhoid fever and that this 50 per cent. should be added to the deaths reported under the heading "typhoid fever" alone.

It is my opinion that the truth lies somewhere between these two extremes and that for one-half of the deaths reported from intermittent fever to all the deaths reported from this cause should be classed as genuine typhoid fever. The proportion undoubtedly varies somewhat from year to year, the number that should be transferred from one column to another probably being less in the last five years or six years than in the earlier period.

On the whole it is my opinion that most epidemiologists and sanitarians would consider that at rurer conception of the ty-

phoid fever mortality in St. Louis would be derived by transferring all the deaths from the remittent, intermittent
10120 column than by transferring only 50 per cent. of the deaths, but that is a matter of opinion simply.

Q. Have you made any studies of comparisons between the typhoid and typho-malarial groups of the City of St. Louis with those of any other cities?

A. Yes sir, I have examined the deaths reported from malaria fever in the City of Chicago from 1851 to the end of 1902, and have recorded them by months in the accompanying table, and have also examined the figures for typhoid fever during this same period.

The table is as follows:

10121

MALARIAL FEVER.

DEATHS AS REPORTED BY MONTHS; TOTALS BY YEARS

Year.	Jan.	Feb.	Mch.	Apr.	May.	June.	July.	Aug.	Sept.	Oct.	Nov.	Dec.	Totals.

10124 I have also examined the deaths reported from typhoid fever and those reported from malarial diseases in the city of Albany, by months, between January, 1891, and December, 1903.

I have also examined the Baltimore figures as I have already mentioned.

Q. If so, please state how they compare?

A. There is the same general correspondence by months and years that has been noted in the St. Louis records. For example, the largest number of deaths reported from malarial fever in Chicago was in the year 1891, the same year when typhoid fever prevailed in epidemic form in this city and caused the largest number of deaths ever reported from this cause.

In general when the deaths reported from typhoid fever are low those reported from, malarial fevers are low and vice versa.

The proportion of deaths reported from malarial fever is lower in the last ten years than in the earlier portion of this period, owing in large part probably to progress in methods of diagnosis.

A very interesting condition is revealed by the monthly
deaths reported from typhoid fever and malarial dis-
10125 eases in the city of Albany, New York.

As is well known a sand filter was put in operation in Albany on September 6, 1899. During the ten years, 1891 to 1899, inclusive, the total number of deaths reported from typhoid fever was 777, or an annual average of 86. For the four years since the filter was put in operation the total number of typhoid deaths has amounted to 106, or an annual average of 26 since the filter was opened as against 86 preceding.

An exactly similar decline is noticed in the number of deaths reported from malarial diseases. Prior to the opening of the filter the deaths reported from malarial fever amounted to 61, an annual average of 7. In the four years since the filter was opened only two deaths in all have been reported from malarial diseases, or an annual average of ½.

The inference is plain that both reported causes of death, namely "typhoid fever" and "malarial diseases," have been affected by the opening of the filter, and the only conclusion that can be drawn is that the deaths reported as occurring from malarial diseases were really cases of genuine typhoid fever.

The strict parallellism between the deaths reported from typhoid fever and malarial diseases in St. Louis, in Chicago, in Baltimore and in Albany demonstrates conclusively to my mind that the confusion in diagnosis already set forth has existed in widely separated localities. This confusion, however, has been less marked in those regions where malaria is less prevalent and where, therefore, physicians would be less likely to resort to it as an explanation of disease and death. 10126

Q. Have you a table of the death rates from typhoid fever in the city of St. Louis?

A. I have.

Q. From what sources did you obtain the data from which the table which you made were compiled?

A. The figures for population were obtained from the United States Census reports for 1890 and 1900, the population for the intervening years being estimated by Farr's formula, as was also that for the years 1900 and 1903.

Q. What is Farr's formula?

A. Farr's formula is a formula well known to vital statisticians, by means of which the increase of population may be estimated on the hypothesis that the population increases in geometrical progression.

It has been found that this method gives results that closely approximate to actual conditions. It has been thoroughly tested in Europe and in this country.

Taking the population as determined by the United States census as a basis and assuming that the increase between these years has proceeded regularly and by geometrical progression, it is a simple mathematical process to determine the population for each year between the two census years. 10127

Q. Upon what did you make the basis of compilation in the tables that you have prepared?

A. I have estimated the death rate per 100,000 inhabitants based upon the figures of population obtained in the way just described, under three heads, namely: For typhoid fever alone as tabulated in the health reports of the city of St. Louis; for typhoid fever, plus 50 per cent of the deaths recorded under remittent fever, intermittent fever, etc., and for typhoid fever plus all the deaths recorded under the head remittent, intermittent fever, etc.

Q. Will you read into evidence the tables which you have prepared?

A. Yes sir. They are as follows:

10128

TYPHOID FEVER DEATH RATES.

ST. LOUIS.

Death Rate per 100,000.

Year..............	Population..........	Typhoid fever alone.	Typhoid fever plus 50 % of deaths recorded under heading intermittent fever, etc..........	Typhoid fever plus all the deaths recorded under the heading intermittent fever, etc. ...
1890	451,709	30.0	56.67	81.2
1891	462,763	35.6	58.98	82.3
1892	474,077	93.0	127.40	161.7
1893	485,668	44.2	73.52	102.7
1894	497,565	34.3	52.24	70.3
1895	509,740	29.9	30.35	51.3
1896	522,225	20.2	37.37	54.1
1897	533,762	23.4	39.53	55.6
1898	548,590	17.3	29.53	41.7
1899	361,510	23.3	36.49	49.6
1900	575,238	29.2	39.07	48.6
1901	589,315	33.5	40.39	47.1
1902	603,736	36.7	45.21	53.6
1903	618,510	46.5	54.0	61.3

10129 Q. Please state what these tables show as to the death rate in the city of St. Louis from 1890 to 1903, based upon the percentage of population?

A. They show a considerable difference in the death rate according to the number of deaths assumed to be deaths from genuine typhoid fever. Considerable variation is exhibited in the three columns during this period, owing to the transfer of reported deaths from the intermittent column to the typhoid column, as already referred to several times in my testimony.

Q. Will you compare the death rate of typhoid fever in St. Louis from 1890 to 1899, inclusive, with that of 1900 to 1903, inclusive?

A. Assuming that the deaths reported under the heading typhoid fever alone during this period were the only deaths that occurred from this disease in the city of St. Louis, the average annual death rate from 1890 to 1899, inclusive, as shown in the detailed table, excluding, however, the year 1892, as being a year of special epidemic prevalence, was 28.8. On the same basis the average annual death rate from 1900 to 1903, inclusive, was 36.5.

Assuming that only one-half of the deaths recorded under the heading intermittent fever, etc., were deaths from genuine typhoid fever, the average annual death rate from 1890 to 1899,
inclusive, excluding as above the year 1892, was 46.07.
10130 On the same basis the average annual death rate from
1900 to 1903, inclusive, was 44.67.

Assuming that all the deaths reported under the heading intermittent fever, etc., were deaths from genuine typhoid fever, an assumption which in my opinion is not very wide of the mark, the average annual death rate from 1890 to 1899, inclusive, excluding as above the year 1892, was 65.4.

On the same basis that from 1900 to 1903, inclusive, was 52.1.

On either of the latter assumptions the death rate from typhoid fever in the four years, 1900 to 1903, was distinctly lower than in the preceding decade, even when the year of maximum typhoid prevalence in that decade is excluded from the estimation.

Q. Assuming that all the deaths in the typhoid column and the typho-malarial column are typhoid, how does the periods 4 years prior to 1900 compare with the period 4 years since 1900 as to whether there is an increase or decrease in the typhoid fever in the city of St. Louis?

A. The annual death rate on this basis is almost ex-
10131 actly the same, being 52.2 for the period of 4 years prior
to the opening of the canal, and being 52.7 for the period of four years since the opening of the canal. With these figures it would be impossible to assert that there has been either an increase or a diminution in the typhoid fever death rate in this period on the assumption just predicated.

Q. Has typhoid fever increased or decreased in the city of St. Louis since 1900 over the conditions that obtained for the 10 years prior to 1900, in the city of St. Louis?

A. It is emphatically my opinion that the average death rate from typhoid fever in the city of St. Louis has been less in the 4 years beginning with 1900 than the average for the preceding decade, excluding in this comparison the epidemic year of 1892.

Q. How does the typhoid fever death rate in St. Louis compare with the death rate in other American cities during this period?

A. Regarding the typhoid fever death rate as reported in St. Louis, from the figures of typhoid fever alone, the death rate is not very different throughout this 14 year period with the death rate in the city of Boston, omitting in this comparison the epidemic of 1892 in St. Louis. In Boston the average
10132 annual death rate from 1890 to 1902, inclusive, as taken
from the official figures in the health reports in the city of Boston was 29.7, while the death rate in St. Louis, as inserted in the column typhoid fever alone during the 14 year period already mentioned, excluding the year 1892, was 31.1, or almost exactly the same as that in the city of Boston during that period.

The water supply of Boston throughout this period has been regarded as being a fairly satisfactory municipal supply. In the city of Lawrence, Mass., before filtration was introduced, the death rate from typhoid fever averaged 120. The death rate in the state of Massachusetts from typhoid fever during the period 1897 to 1902 was 40, or considerably higher than that in the city of St. Louis, for the period just indicated. In 1894 the death rate in the city of Lawrence was 48 and in 1899 it was 33.

Considering the real death rate in the city of St. Louis from typhoid fever to be represented by the death rate computed on the total of the two headings, typhoid fever and intermittent fever, the death rate in this city throughout nearly the whole period under consideration has been excessive and higher than ought to exist in a city provided with a pure water supply.

10133 Q. Is there any reason other than those you have given for supposing that the number of typhoid fever deaths in St. Louis is higher than that indicated by the figures recorded under heading typhoid fever alone?

A. Yes, I think the fact that I have just instanced regarding the death rate in other American cities is a very strong reason for believing that the actual number of typhoid fever deaths in St. Louis is higher than that indicated under the heading typhoid fever alone. Knowing what I do of the source of the St. Louis public water supply and of the character of the water shed of the Missouri, Mississippi and Illinois Rivers for some distance above the water intake I should expect that a city supplied with a non-filtered surface water of the character of the Mississippi River water at the intake tower at St. Louis would give rise to a higher death rate from typhoid fever than is indicated by the figures under the heading typhoid fever alone in the St. Louis health reports. The death rate from typhoid fever in St. Louis as reckoned on the total of typhoid deaths and typho-malarial deaths is, in my opinion, much nearer what would be anticipated from a consideration of the character of the Mississippi River water than the death rate as reckoned from the so-called typhoid fever deaths alone.

10134 Q. Professor, from a careful analysis of the typhoid and the typho-malarial mortality statistics as they appear in the board of health reports of St. Louis and your knowledge of the conditions that obtain in other cities using a water supply from a river,as well as all other sources of knowledge which you possess upon this question what is your opinion as to whether there has been an increase in typhoid fever in the city of St. Louis since January 17, 1900, over the average typhoid conditions that prevailed in St. Louis for ten years prior to that time?

MR. JEFFRIES: I object to the question for the reason that the number of years to be compared are not the same in point of number, the duration of the periods to be compared are not the same and for the further reason that during a portion of one period, to-wit: from 1890 to 1895 the water supply of the city of St. Louis was not taken at the same point and the manner of taking was not the same as it has been since that period.

A. In consideration of all the facts regarding the mortality of typhoid fever in the city of St. Louis during the period indicated that can be obtained from the official records as published it is my opinion that the average annual death rate from typhoid fever in that city has been lower for the four years 1900 to 1903 than for the preceding decade, excluding the epidemic year of 1892.

10135 Q. Assuming the same conditions in the previous question, what is your opinion as to whether there has been an increase of typhoid fever in the city of St. Louis since January 17, 1900 down to 1903, inclusive, over the general typhoid conditions that prevailed in St. Louis for the 4 years prior to 1900?

A. From the facts already cited which embody all the information that I have been able to obtain, and from a critical analysis of the figures presented in the reports of the health department of the city of St. Louis I conclude that there has been no increase in the annual death rate from typhoid fever in the city of St. Louis since January 17, 1900, as compared with the average annual death rate for the 4 years preceding 1900. As shown in my answer to a previous question the death rate for these two periods computed on the assumption that the typhoid fever deaths and the typho-malarial deaths should be considered as a whole, is almost exactly the same.

Q. What is your opinion based upon all the information and knowledge that you have in regard to the typhoid conditions of the water sheds above the St. Louis intake at the chain of rocks as to whether the typhoid conditions that have prevailed in St. Louis since January, 1900, are due directly to the opening of the Chicago Drainage Canal which took place on January 17, 1900, wherein the sewage of Chicago was emptied into the Desplaines and Illinois River?

10136 MR. JEFFRIES: I object to the question for the reason that the witness has not yet stated what knowledge he has with reference to the conditions of the water sheds above the chain of rocks.

MR. TODD: In reply to the objection I will state that it is a matter for counsel to bring out on cross-examination if he entertains any doubt as to the witness' knowledge of the typhoid conditions as mentioned in the question.

MR. JEFFRIES: I suggest to counsel that ordinarily that might be true, but when this witness undertakes to testify as an expert he must first show sufficient qualification upon which to base his expert testimony and unless that be shown in the evidence the question and any answer given thereto would be incompetent and irrelevant.

MR. TODD: I submit that it is a question for the court to decide whether this witness is qualified to answer the question.

MR. JEFFRIES: That is always a question for the court to decide.

Q. Question repeated.

A. It is my best judgment based upon all the information of which I have become possessed that no portion of the typhoid fever mortality occurring in St. Louis since January, 1900, can be attributed directly or indirectly to the opening of the Chicago Drainage Canal.

10137 Q. Are you acquainted with the typhoid conditions that obtain along the Missouri and Mississippi Rivers above the intake of the St. Louis waterworks as well as those that obtain along the Illinois, the conditions of typhoid in St. Louis and the conditions of typhoid fever in Chicago?

A. I have already submitted the information that I possess regarding the typhoid conditions of Chicago and St. Louis. I have here tables showing the deaths reported from typhoid fever in the principal cities on the Mississippi River above Grafton, the Missouri River and the Illinois Rivers for the years 1893 to 1902, inclusive.

Q. Is there any connection in your opinion between the typhoid condition that has prevailed in St. Louis since the opening of the drainage canal and the discharge of the sewage of

Chicago through the drainage canal since January 17, 1900?

A. In my opinion no such connection exists.

Q. Will running water purify itself so as to be free from pathogenic bacteria that might have been placed therein?

A. Running water, like still water, will rid itself of pathogenic bacteria after a sufficient time. The factor of time rather than distance influences the disappearance of pathogenic microbes. There is satisfactory evidence that a flowing stream becomes freed from large numbers of sewage bacteria that are introduced into it, and since many of these sewage bac-
10138 teria are much more resistant than most pathogenic microbes it follows that the rate of disappearance of the latter is probably more rapid than that of the harmless sewage bacteria. A remarkable instance of the disappearance of sewage bacteria in running water is furnished by the condition of the Mississippi River at New Orleans. Although the sewage of the whole interior of the North American continent enters the Mississippi River and its tributaries the number of colon bacilli, the most characteristic bacteria of sewage at New Orleans is so small that from this standpoint the water compares favorably with many filtered waters and indeed many pure spring waters. The evidence on the whole is overwhelming that running water, like standing water, can and does purify itself.

Q. This question was asked of Professor Sedgwick on page 3448 of my transcript of record, and I desire to ask the same question of you. "State your opinion as an expert on water supplies for cities and towns as to whether or not the waters of the Mississippi River west of the center thread of the main channel of said river below the mouth of the Illinois River and down to the intake tower of the St. Louis waterworks at the chain of rocks is less valuable for drinking purposes and more liable to carry water-born diseases such as typhoid fever and cholera now than it was before the sewage from the sani-
10139 tary district of Chicago was run into the drainage canal and through it into the Illinois River?"

A. It is my opinion that the waters of the Mississippi west of the center of the main channel of the river below the mouth of the Illinois River and down to the intake tower of the St. Louis waterworks at the chain of rocks are no less valuable for drinking purposes nor more liable to carry water-borne diseases than they were before the sewage of the sanitary district of Chicago passed through the drainage canal and through it into the Illinois River. I hold this opinion for the reasons that I have already set forth in considerable detail in my previous testimony, namely that it is my judgment that typhoid bacilli will not live long enough in the waters of the drainage canal or Illinois River to travel from Chicago to St. Louis and furthermore that the change in conditions in the Illinois River since the opening of the drainage canal has not been of a character to justify the assumption that the conditions for the longevity of the typhoid bacillus have been materially improved.

Q. With reference to the quantity of water in the Illinois River do you know what proportion the added volume from the drainage canal will bear to the waters of the Illinois?

A. The proportion of water coming from the drainage canal to the total flow of the Illinois River varies of course considerably from year to year and from season to season,
10140 resulting from the variation in the amount of rainfall and run off. When the Illinois River is high the flow from the drainage canal may amount to not more than one-tenth of the total discharge of the Illinois River, and at times of low water the flow from the drainage canal may amount to possibly as much as one-half of the discharge.

Q. This question, page 3450 of my transcript of the record, was asked of Professor Sedgwick and I desire to ask it of you. "State whether or not an increase in the speed of the current of the Illinois River by reason of the added volume of the water of the drainage canal would affect the amount of sedimentation that might otherwise occur in the Illinois River and if it does effect it, how and in what manner?"

A. I have seen no reason to think that the added volume of water from the drainage canal would materially affect the amount of sedimentation occurring at most seasons in the Illinois River, since the speed of the current in the river appears to be but slightly affected by the increased discharge from the drainage canal. The increased volume leads rather to the spreading out of the river into the low-lying banks and sub-

jacent meadows thus affording additional opportunities
10141 for sedimentation rather than leading to a scouring of
the channel.

Q. This question was asked Professor Sedgwick on page 3450 of my transcript of the record, and I desire to ask you the same question. "What effect, if any, would the increase in the speed of the current in the Illinois River have upon the time within which the sewage from Joliet, Peoria and other towns on the Illinois River might be removed into the waters of the Mississippi (if the same are so removed) as compared with the conditions that existed and the time it might have taken before the added volume of water from the drainage canal was poured into the waters of the Illinois?"

A. The analyses and examinations that have been made of the water of the Illinois River at its mouth do not in my opinion show that the opening of the drainage canal has caused the sewage from Joliet, Peoria and other towns of the Illinois River to be hurried into the waters of the Mississippi River any more rapidly than was the case before the added volume of water from the drainage canal was poured into the waters of the Illinois.

Q. I will ask you this question which was asked of Professor Sedgwick on page 3451 of my transcript of record: "If the water is made more clear and less turbid than it was before the added volume of water being placed therein, will such bacilli
as typhoid have more or less tendency to go down to the
10142 bottom of the stream than they had prior to the water
being rendered less turbid?"

A. There is no doubt that the presence of large quantities of suspended matter in the water of a sluggishly flowing stream tends to facilitate the sedimentation of such bacteria as may be present in the waters of that stream. The life of the typhoid bacillus, however, is so short under the conditions presented in such waters that it makes very little difference whether this organism perishes while suspended in flowing water or dies out in the sediment deposited in the bottom of such stream. Despite the dilution of the water of the Illinois River with the less turbid water from Lake Michigan it is my opinion that the life of the typhoid bacillus would not be increased by such addition.

Q. This question was asked of Professor Sedgwick on page 3452 of the record that I have, and I desire to ask it of you: "If an increased volume of water in the Illinois by the addition of the water of the drainage canal would make an increased speed in the current of the Illinois River would that increase in said current have the effect of increasing or diminishing the typhoid and liability to typhoid and other water-born diseases on the part of the inhabitants of the State of Missouri using the water of the Mississippi River for drinking purposes
10143 below the mouth of the Illinois River?"

A. I do not think that such increased speed as might reasonably be assumed to result from the opening of the drainage canal would increase in any degree the liability to typhoid and other water-born diseases of the inhabitants of the State of Missouri for the reason that such shortening of the time involved as might legitimately be assumed to occur would not come within the range of longevity of a typhoid bacillus under these conditions. It is undoubtedly true that the typhoid bacillus can live longer in relatively pure water such as a lake, well or cistern than in water containing numbers of sewage bacteria. It is generally believed to be true that the rapid mortality of typhoid bacilli in unsterilized water is due to the action of the toxic products of other microbes, which are in sewage polluted water, the toxic products are there present in a more concentrated condition and the typhoid bacillus therefore is acted on by them more speedily.

Q. Professor Sedgwick in answer to this question on page 3453 of my transcript of the record: "What do you say as to the longevity of the germ of typhoid fever as a general proposition in connection with sewage polluted water," answered, "Here also our ideas have undergone some change of late years; my ideas have undergone some late change. Broadly speaking the tendency has been to come to the belief or has been to show or to indicate a greater and greater longevity. Laboratory
10144 experiments have sometimes indicated a short and sometimes a longer longevity. Practical experience has tended to make us believe in a greater longevity than that form-

erly entertained, and having reference to the conditions in the stream, the various conditions in streams, my belief is that in a sewage polluted stream a typhoid germ might live in gradually diminishing numbers for weeks or months or even years." What is your opinion as to the correctness of that belief based upon your knowledge as a bacteriologist and sanitarian?

A. I know of no evidence that indicates that in a sewage polluted stream typhoid bacilli might live for years, months or even weeks. On the contrary all the evidence that I am familiar with regarding the life of typhoid germs in water, even under the very favorable conditions present in sterilized water, in glass flasks in a laboratory shows that this organism is not only not able to multiply under these conditions, but that it diminishes rapidly and steadily. If it were true that the typhoid bacilli could persist for such long periods in the water of reservoirs and settling basins the epidemiological evidence would, I think, indicate that this is true. So far from this being the case a sudden change in conditions such a diversion of sewage away from the water supply usually leads to a
10145 marked improvement in the typhoid fever conditions. An appropriate illustration of this is afforded in the case of the opening of the Chicago Drainage Canal which was followed in the ensuing twelve months by the lowest death rate from typhoid fever ever recorded in the sanitary history of Chicago. This would hardly have been the case if the typhoid germs which had been poured into Lake Michigan in what we must believe to be considerable numbers, during several decades had persisted for any lengthy period in the sediment of the waters of the lake.

ADJOURNED until 10:00 a. m., February 11, 1904.

10146 10:00 A. M., Thursday, February 11, 1904. Continuation pursuant to adjournment. Present, the Commissioner and same counsel representing the respective parties.

PROF. EDWIN O. JORDAN

resumed the stand for further direct examination by Mr. Todd, and testified as follows:

Q. This question was asked of Professor Sedgwick, on page 3454 of the transcript of the record that I have, and I desire to ask it of you. Assuming that the number of bacilli coli communis in the waters of the Illinois River at Grafton are at intervals no greater than the numbers contained in it above the opening of the drainage canal, do you consider for that reason that the water is at all times no more dangerous than formerly?

A. In my opinion, and I believe in that of bacteriologists generally, the presence of colon bacilli in water affords a satisfactory clue to the amount and freshness of sewage pollution.

Since it is true that the number of colon bacilli now found in the water of the Illinois River at Grafton is no greater 10147 than the number found in the water at this same place before the opening of the drainage canal, I am certainly compelled to conclude that the character of the water and its liability to contain typhoid germs has not been materially changed and that the water is no more dangerous than formerly.

Q. Professor Sedgwick, on page 3454 of the transcript of the record which I have, in answer to the following question: "Assuming that the germs of typhoid fever coming from the sewers of Chicago, and passing by way of the drainage canal to Lake Peoria, be in large numbers deposited in the bed of Lake Peoria for the period of a month say, do you consider that typhoid germs would be entirely destroyed at the end of that time, in that deposit" answered "no sir." What do you say as to the assumption that typhoid germs could pass from the sewers of Chicago by way of the drainage canal to Lake Peoria and be deposited there in the bed of Lake Peoria for a period of a month, and as to whether or not typhoid germs coming through the drainage canal, under the conditions as they exist today, would live for a period of a month and not be destroyed before the end of that period?

A. From all that I have been able to learn concerning the life history of the typhoid germ in water, it is my opinion that it is most improbable that typhoid germs would live long 10148 enough in the Illinois River to pass from Lockport to Lake Peoria. In case of such an extremely unlikely occurrence any such typhoid germs deposited on the bed of Lake Peoria would in my judgment be in an extremely weakened condition and would not be likely to live for more than a few hours.

It is my opinion that there certainly would be no accumulation of bacilli under these conditions.

Q. Professor Sedgwick, on page 3455 of the transcript of the evidence which I have, in answer to the question "assuming that typhoid fever germs coming from Chicago sewers are deposited in large numbers in the lakes and slack water portions of the Illinois River above Peoria, do you or do you not consider that flood conditions such as would scour the deposits from the beds of the streams would cause the water leaving Lake Peoria to contain at times more infectious and dangerous pollution than is at present in the diluted sewage entering at the Bear Trap Dam at the foot of the drainage canal" answered "I think that at times it might." Question "Why?" answer "Because if accumulations of typhoid germs were found in the lakes or slack water basins of the river, these might, especially in the case of a large amount of typhoid fever in Chicago, result in the storage of a vast number of germs and with a
10149 sudden flood might sweep out these accumulations and
actually bring it about that sometimes more typhoid fever germs would be flowing in that stream than in the drainage canal itself." What is your opinion, taking into consideration all that you know about the conditions in the drainage canal, the Desplaines river and the Illinois river, as a bacteriologist and sanitarian as to whether such a condition at that time might or does exist?

A. It is my opinion, taking into consideration all that I know about the conditions in the drainage canal, the Desplaines river and the Illinois river, and taking into consideration all the facts that I have been able to obtain by personal investigations and by examination of the leading authorities in the matter, that typhoid fever germs live so short a time under the conditions enumerated that there is no danger that the water that leaves Lake Peoria can at any time contain more infectious material, or, specifically, more living typhoid bacilli than exist in the diluted sewage flowing from the Bear Trap Dam at the foot of the drainage canal.

Q. What is your opinion as to whether typhoid fever germs coming from the Chicago sewage are deposited in large numbers in the lakes and slack water portions of the Illinois river, above Peoria?

10150 A. It is my opinion that typhoid fever germs coming from Chicago sewage rarely, if ever, live long enough to reach Averyville, and it is consequently my judgment that such germs can not be deposited in large numbers in the lakes and slack water portions of the Illinois river above Peoria.

Q. What is your opinion, based upon all the knowledge which you have, as a chemist and bacteriologist and sanitary expert, as to whether at any times of the year under any conditions of water in the Illinois river the number of typhoid fever germs at that point is ever as great as they are at the Bear Trap Dam at the end of the drainage canal?

A. It is emphatically my opinion that the number of typhoid germs in the water of the Illinois river and Lake Peoria is never as great as the number in the drainage canal near the Bear Trap Dam at Lockport, and furthermore that the assumption that they are is not, so far as I am cognizant of the facts, borne out by any data, chemical, bacteriological or epidemiological.

Q. Do you know of any evidence based upon any investigations made by yourself or by any one else that justifies the conclusion that at one time, under any conditions, there are a larger number of typhoid fever germs at Lake Peoria than at the Bear Trap Dam at the foot of the drainage canal?

A. I know of no evidence based upon any investigation that I have made or that have been made by any bacteri-
10151 ologist in any part of the world that justifies the conclusion that there are larger numbers of typhoid fever germs in Lake Peoria than in the water of the drainage canal at the Bear Trap Dam at Lockport. On the contrary, from all the information that I have been able to obtain, I am satisfied that there is a much smaller proportion of typhoid fever germs in the water of Lake Peoria than in the water of the drainage canal at the Bear Trap Dam. In my opinion such typhoid fever bacilli as may be present in the waters of Lake Peoria are not derived from the sewers of Chicago but come from sources much nearer this point.

Q. Do you know of any evidence, scientific or otherwise, that shows that accumulations of typhoid germs are found in lakes or slack water basins of rivers and remain there in storage in vast numbers for any considerable period of time in a virulent state, and are suddenly flooded out by freshets so that greater numbers of typhoid fever germs are present, flowing in a stream a considerable distance from the source of pollution itself than they exist at the source of pollution?

A. I not only know of no evidence that indicates that accumulations of typhoid fever bacteria take place in lakes or
slack water basins of rivers and remain there in storage,
10152 but on the contrary it is my opinion that the evidence
available on this point shows distinctly that no such accumulations take place. It is my belief, as already stated in my testimony, that typhoid germs introduced into sediment under these conditions speedily perish and would not survive so long in a virulent state that they could at some future time be flushed out from such slack water basins.

Q. Has the removal of deposits of sewage matter from the beds of streams resulted in causing typhoid epidemics, and do you know of any well established authenticated case where the cause of the epidemic was established as being due to the removal of deposits of sewage matter from the beds of streams beyond all reasonable doubt?

A. It is possible that where deposits of sewage matter are fresh and recent, as they are, for example, in the bed of the Chicago river, that the sudden flushing out of such a stream might lead to an outbreak of typhoid fever within two or three days distance from such deposits. But where sewage matter has been deposited on the bed of a stream and allowed to remain there for a period of several weeks, without receiving any addition of fresh material, I know of no instance where an epi-
demic of typhoid fever has been traced beyond all rea-
10153 sonable doubt to the removal or flushing out of deposits
of such sewage matter.

Q. Have you studied and are you acquainted with the facts upon which the conclusion has been arrived at that the Detroit epidemic was caused by the dredging of the Black river at Port Huron?

A. I have read the testimony that has been given in this case regarding the dredging of the Black river at Port Huron and its supposed connection with the outbreak of typhoid fever in Detroit.

Q. From your knowledge as an epidemiologist do you consider the cause of the epidemic at Detroit has been established as coming from the Black river at Port Huron beyond a reasonable doubt?

A. I do not for the reason that other sources of infection have not been eliminated, and moreover it is my opinion as a bacteriologist and epidemiologist that under the conditions as described typhoid bacilli could not travel from the Black river at Port Huron to Detroit in sufficient numbers and in a sufficiently virulent condition so that they would be capable of causing an outbreak of typhoid fever in the latter place.

Q. This question was asked of Professor Sedgwick on page 3457 of my transcript of the record, and I desire to ask it of you: "Now, assuming that the only pollution of the Illi-
10154 nois river was that contributed to it by the Chicago Sanitary District and having in mind a large amount of typhoid fever in said district, do you or do you not consider the effects of the time interval, dilution and sedimentation occurring between Chicago and Grafton would be such as to render the water as it reaches the Mississippi at all times free from liability of producing water borne diseases to those who drink it?

A. It is my opinion, assuming that the only pollution of the Illinois river was that contributed by the Chicago Sanitary District, and considering the presence of dilution, of sedimentation and particularly of the time interval occurring between Chicago and Grafton, that these would be factors of sufficient power to render the water of the Illinois river as it empties in the Mississippi river free from the liability of introducing typhoid fever or any other water-borne disease among those drinking such water.

Q. Assuming that no other pollution or infection enters the Illinois river save that which it receives from the Sanitary District of Chicago. From your knowledge as a chemist, bacteriologist and sanitary expert and epidemiologist, have you had any reasons, experience or knowledge which would lead you to believe that the waters of the Illinois river at
10155 Grafton is infected with the sewage from Chicago, and if said water at Grafton enters the Mississippi river, becoming mixed with the latter would the Illinois river water be a menace to the health of the inhabitants of the State of Missouri using said Mississippi river water mixed with the Illinois river

water for drinking purposes at points on the Missouri shore?

A. From all the knowledge that I have, I have formed the opinion that the water of the Illinois river at Grafton does not contain infectious elements derived from the sewage of Chicago, and that consequently such water reaching the Mississippi river and becoming mixed with that water is not a menace to the health of the inhabitants of the State of Missouri, on the Missouri shore of the Mississippi river or to the citizens of St. Louis.

Q. Is there anything, based upon your knowledge as a chemist, bacteriologist and sanitary expert which you know that would lead you to believe that the water coming from the Illinois river at Grafton was infected from the sewers of Chicago, and assume that the waters from the Illinois river mixed with the water of the Mississippi river at Grafton, and subsequently mixed with the waters of the Missouri river at its mouth,
10156 do you consider the water of the Illinois river, thus commingled with the waters of the Mississippi and Missouri rivers a menace to the inhabitants of the State of Missouri, upon the Missouri shore of the Mississippi river, using the Mississippi river water for drinking purposes at points below on the Missouri shore?

A. In reply to this I would state that my position is as already stated in answer to the preceding question, namely, that in my judgment no such effect exists.

Q. Is there any evidence, chemical, bacteriological, or otherwise, that can establish the conclusion that the waters of the Illinois river at Grafton are infected by the sewers from Chicago, eliminating all other sources of infection?

A. I know of no evidence that indicates, directly or indirectly that the waters of the Illinois river at Grafton are infected from the sewers of Chicago, and in view of the large amount of pollution of the Illinois river that takes place at points less remote from its mouth than Chicago, it is my opinion that convincing evidence of such infection coming from Chicago would be very difficult if not impossible to secure.

Q. This question was asked Professor Sedgwick, on page 3463 of the transcript of the record which I have, which
10157 I desire to ask you: "Now, assuming that the only pollution upon the watershed of the Mississippi and its

tributaries above the intake of the St. Louis waterworks was that derived from the sewage district of Chicago, and having in mind a large amount of typhoid fever in Chicago, do you or do you not believe that infection and dangerous pollution might under existing conditions find its way into the water supply of the City of St. Louis?

A. I do not believe that infections or dangerous matter passing into the sewers of Chicago finds its way, under existing conditions, into the water supply of the City of St. Louis for reasons which I have set forth previously in great detail.

Q. This question, on page 3463, was asked of Professor Sedgwick which I desire to ask of you: "Assuming that there was no typhoid fever pollution of the waters upon the watershed of the Mississippi river or its tributaries above the intake of the St. Louis waterworks other than that derived from the sanitary district of Chicago, do you or do you not believe that typhoid fever germs from said district are liable to find their way into the water supply of the City of St. Louis through the intake at the chain of rocks?"

A. Assuming that there was no typhoid fever pollution of the waters of the watershed of the Mississippi river or its 10158 tributaries above the intake of the St. Louis waterworks other than that derived from the sanitary district of Chicago, I certainly do not believe that typhoid fever germs from said district would be liable to find their way under existing conditions into the water supply of St. Louis.

Q. Professor Sedgwick, in answer to the foregoing question, stated: "I believe that they are liable to find their way into the intake" and when asked why, answered, "For the reason that typhoid fever having been frequently abundant in the City of Chicago, I must state with the assumption that a very large number of typhoid germs find their way into the sewage of the city, pass through the sewers and on into the drainage canal and subject to local conditions may, in diminishing numbers, pass out of the Illinois river, mingle with the waters of the Mississippi, pass over to the other side and find their way into the intake at the chain of rocks." I want to ask you, Professor, do you know of any evidence based upon any analysis, experiments or otherwise that justify the assumption that typhoid fever germs will pass from Chicago, out of the Illinois river, into the Mississippi river, thence to the chain of rocks and the intake tower of St. Louis?

MR. JEFFRIES: I move to strike out all that part of 10159 the question except the latter sentence which elicits from the witness whether he knows of any evidence of any character whatever that would lead one to believe that typhoid bacilli pass from Chicago to the intake tower of the water supply of the City of St. Louis, for the reason that whatever this witness may say with reference to that part moved to be stricken out will be merely a comment upon the evidence, and that portion of the question moved to be stricken out is a comment upon the evidence and incompetent, irrelevant and not a proper question.

MR. TODD: In reply, will state that counsel correctly interprets the purpose for which the question is asked as is perfectly competent to ask this witness as to the assumption, not the belief as counsel stated, but the assumption carried in the answer of Professor Sedgwick.

MR. JEFFRIES: I move to strike out the suggestion of counsel for the same reason stated in my objection or motion to strike out the question, that it is for this witness as an expert to give his opinion upon facts as he sees them and for the court to determine the weight of the testimony of the respective witnesses and not for themselves to understake to determine the particular weight or credit that should be given each others testimony.

A. I have myself made a number of analyses, experiments, and observations upon the waters of the drainage canal, 10160 the Illinois and Mississippi rivers, and have examined with some care the reports of analyses, experiments and observations made by others, and I have been unable to discover any evidence that justifies the assumption that typhoid fever germs can or do pass from Chicago out of the Illinois river into the Mississippi river, thence to the chain of rocks and the intake tower of St. Louis.

Q. This question, on page 3465, was asked of Professor Sedgwick, and I desire to ask it of you: "Assuming that an epidemic of Asiatic cholera should occur in the City of Chicago, is it possible that the germs of that disease might find their way into the intake tower of the St. Louis waterworks at the chain of rocks, from the City of Chicago?"

A. The germs of Asiatic cholera are less hardy than the germs of typhoid fever and in view of the conditions that have been shown to exist regarding the life of the typhoid fever bacilli in the waters of the drainage canal, it is my opinion that it is most improbable that germs of Asiatic cholera could travel from Chicago to St. Louis by way of the Illinois and Mississippi rivers.

Q. I want to ask you this question which was asked of Professor Sedgwick, page 3470 of the transcript which I have:

"Now, Professor, considering your personal knowledge as 10161 an expert of typhoid fever conditions in the sanitary district of Chicago, under existing conditions in said district as to sewers and the outfalls there are and the amount of sewage and all the existing conditions of the Desplaines, Illinois, Mississippi and Missouri rivers, and all conditions existing upon the watershed of said streams and the tributaries thereof, and all existing conditions as to the water supply of the City of St. Louis and the general sanitary conditions existing in the City of St. Louis, would you or not beyond a reasonable doubt attribute the principal portion of the increase of typhoid fever in St. Louis, since the opening of the drainage canal, to the infected sewage of the sanitary district of Chicago?"

A. I certainly should not.

Q. Why?

A. Assuming that there had actually been a marked increase in typhoid fever in St. Louis since the opening of the drainage canal, which appears to me to be contrary to the fact, it would, in my opinion, be more reasonable and significant to attribute such an increase in typhoid fever to other causes, such, for example, as an infection of the water supply nearer the water intake, to infection of the milk supply or to some other factor rather than to infected sewage coming from the sanitary district of Chicago.

10162 Q. Professor, do you consider that the Illinois river water, containing the mixed sewage and canal water from the Chicago drainage canal, since the opening of the drainage canal, has rendered less safe and wholesome now than before the opening of the canal, for drinking purposes on the part of the inhabitants of the State of Missouri, the waters of the Mississippi river below the mouth of the Illinois river?

A. It is my opinion and judgment that the chemical, bacteriological and epidemiological evidence is altogether convincing that the water of the Illinois river at its mouth is no more unsafe and unwholesome now than it was before the opening of the canal, and that consequently the water of the Illinois river since the opening of the canal has not rendered less safe and wholesome the waters of the Mississippi river below the mouth of the Illinois river.

Q. This question was asked Professor Sedgwick, on page 3486 of my copy of the evidence, which I desire to ask you: "Now, Professor, I will get you to state whether or not in your opinion the liability to contract typhoid fever or other water borne diseases on the part of the inhabitants of Missouri using the Mississippi river water for drinking purposes, below the mouth of the Illinois river, by reason of the sewage from 10163 the drainage canal infecting the water of the Illinois river is constant, immediate and continuous under all existing conditions upon the Mississippi, the Desplaines, the Illinois and the Missouri rivers, and the tributaries of said streams, under all existing conditions, upon the watershed of the said rivers and the tributaries thereof and the drainage canal and the sanitary district of Chicago?

A. It is my best judgment that the inhabitants of Missouri, using the Mississippi river water below the mouth of the Illinois for drinking purposes are not, under existing conditions, liable to contract typhoid fever by reason of sewage from the Chicago drainage canal infecting the waters of the Illinois river.

Q. Professor Sedgwick, on page 3495, in answer to a question, among other things, answered, "The mere presence of pollution, I mean by that disinfected sewage, that, is, supposing Chicago reduced her typhoid rate and could still put her sewage down there, that sewage as affecting the longevity or growth of germs which go in from Peoria or anywhere else would be an added menace to cities with water supply, even if she did not send typhoid fever germs down, sending the filth alone down is serious." I will ask you what is your opinion based upon your experience as a bacteriologist and sanitarian that the sewage from Chicago favors the longevity or growth of germs from

Peoria or anywhere else, emptying their sewage into
10164 the Illinois river?

MR. JEFFRIES: I object to that because it is incompetent and immaterial.

A. On the contrary, it is my opinion that the introduction of sewage or organic matter of a similar character into the river water is distinctly detrimental to continued longevity or growth on the part of the typhoid fever bacillus. In my judgment the experiments carried out upon the life of the typhoid fever bacillus in the waters of the drainage canal show that the presence of a considerable amount of organic matter or sewage in the water favors the speedy dying out of typhoid fever bacilli, rather than their continued vitality. As I have alread pointed out this is what might be anticipated in view of the greater concentration of the toxic products of saphrophytic microbes in waters highly charged with organic matter than in purer waters.

This being the case it would follow that typhoid fever germs passing into the river from Peoria would not be favored in any respect by the fact that Chicago sewage had entered the Illinois valley 150 miles above. On the other hand they might be actually injured by the products originating from the decomposition of such sewage which were carried down even as
10165 far as Peoria.

Q. Does the presence of sewage in water add to the longevity or growth of pathogenic bacteria?

A. I have already stated that I considered the presence of sewage in water under natural conditions does not add to the longevity or growth of pathogenic germs but favors their speedy dying out.

Q. Professor Sedgwick answered this question, on page 3496, which I desire to ask you: "Do you or not consider that the Illinois river water, polluted and infected by the sewage from the Chicago sanitary district, since the opening of the drainage canal has rendered less safe the water supply of the City of St. Louis as drawn at the intake tower at the chain of rocks and upon what do you base your opinion?"

A. I do not consider that any pollution or infection with sewage from the Chicago sanitary district, since the opening of the drainage canal, has rendered less safe the Illinois river water at its mouth or in consequence the water supply of the

City of St. Louis as drawn at the intake tower at the chain of rocks.

I base my opinion upon all the testimony that I have submitted in this case and upon all the information of every kind chemical, bacteriological and epidemiological, that I have been able to secure.

10166 Q. This question, on page 3497 of my record, was asked of Professor Sedgwick, which I desire to ask of you: "Assuming that the population of the sanitary district of Chicago covers about 3,000,000 people and that the flow through the drainage canal reaches 600,000 cubic feet a minute, what in your opinion would be the effect upon the water of the Illinois river as compared with that water at its mouth as found during the past three years?"

A. I do not believe that the sanitary quality of the Illinois river water at its mouth would be affected by a change in conditions such as that indicated in the question.

Q. This question was asked of Professor Sedgwick, on page 3498 of the testimony, which I have, and which I desire to ask you: "Assuming that the Chicago sewage from 1,500,000 people living in the sanitary district and city of Chicago should be discharged into the Chicago canal and carried from the canal to the Desplaines river and thence into the Illinois river, Chicago being 357 miles from the St. Louis intake, and assuming that a typhoid fever epidemic of extraordinary proportions should become prevalent among the residents of the sanitary district of Chicago at a time when the sewage from said district is being so discharged into the canal, what immediate and impending danger would exist and what effect would it have on the people 10167 of St. Louis and those people living on the Missouri side of the Mississippi river below Grafton, who use the waters of the Mississippi river for drinking purposes?"

A. I know of no reason for believing that typhoid fever germs discharged into the sewers of Chicago, even in immense numbers, could travel down the Illinois river and affect the quality of the water and the health of the people of St. Louis. On the contrary, under existing conditions, the evidence is to my mind strongly in favor of the view that all the typhoid bacilli introduced into the waters of the Chicago river from the sewers of Chicago, perish before the flow from the drainage canal reaches Averyville.

Q. This question was asked Professor Sedgwick, following the last question, which I desire to ask you: "Now, Professor, assuming the same conditions as in the last question you have been answering, and assume that instead of an extraordinary typhoid fever epidemic prevailing in the sanitary district of Chicago, a cholera epidemic should prevail in the sanitary district of Chicago, a severe cholera epidemic should prevail in the sanitary district, would the danger be imminent, impending and immediate to the people of Missouri below Grafton who used the waters of the Mississippi for drinking purposes, as far down as the chain of rocks?

10168 A. The statements that I have already made regarding my opinion as to the life of the typhoid bacillus in the waters of the Illinois river, under existing conditions, apply with even more force to the possible longevity of the cholera spirillum. The danger in my opinion would not be imminent, impending or immediate to the people of Missouri below Grafton who use the waters of the river for drinking purposes, but would on the contrary be imaginary, hypothetical and nonexistent.

Q. What in your judgment was the sanitary character of the water supply at St. Louis after having passed through the settling basins as delivered to the subscribers during the years 1895 to 1899, inclusive, and upon what do you base your conclusions?

A. It is my judgment that the water supply of the City of St. Louis, during the years 1895 to 1899, inclusive, was not a satisfactory municipal supply. I base this opinion upon the great amount of typhoid fever in the city, as shown by the considerable number of deaths reported during this period from typhoid fever or typho malarial fever and other infections which are properly to be classed as typhoid. Taking these into consideration the typhoid fever death rate during the years mentioned was much higher than ought to be the case in a
10169 city having a pure and satisfactory water supply.

Q. What is your opinion as to the satisfactory character of the water of St. Louis since 1899?

A. In my opinion the character has been substantially the same since 1899 as before that year, except that the increasing population in the towns and villages and rural communities immediately above St. Louis, on the Missouri, Mississippi, and Illinois rivers has had the effect of somewhat increasing the degree of pollution.

The mortality from typhoid fever in St. Louis in 1902 and 1903 was somewhat greater than in the years immediately preceding.

Q. State in detail what position the science of bacteriology occupies in regard to the ascertainment of the purity of river waters ?

A. In my opinion bacteriology affords a very valuable service to the sanitarian engaged in the consideration of the character of waters. The colon test represents, in my opinion, the most satisfactory single test for determining the wholesomeness of natural water. The information derived from this and other bacteriological tests should, however, be supplemented by chemical, epidemiological and other data where these can be ascertained.

10170 Q. What position does the science of bacteriology occupy in what is known as sanitary science?

A. Bacteriology constitutes in a sense the foundation and basis of all sanitary science, since the infectious diseases with which sanitary science is particularly concerned are germ diseases. The best known of these germ diseases are due to bacteria of various kinds, and not only the nature of the infecting organism, but the vehicle of infection, the channel of entrance into the body and other factors depend for their distinction upon bacteriological data.

Q. State in detail what place the science of chemistry holds in regard to the ascertainment of the purity of river waters?

A. The data derived from the chemical analysis of river water are often very important in enabling a sanitarian to form an independent judgment as to the character of a water. The various stages of organic nitrogenous matter, the amount of chlorine and other elements furnish oftentimes a very good indication of the changes that have taken place in polluted river waters, and from this as a basis correct inferences can be drawn as to the degree of self-purification that has occurred.

Q. What position does chemistry occupy in what is known as sanitary science?

10171 A. In addition to supplementing the bacteriological examination of river water the study of chemistry affords data that sheds light upon many of the general problems of sanitary science. In general, applications to the problems of bacteriology chemistry has been found particulary useful and important.

Q. In the ascertainment of the quality of river water what aid is chemistry and bacteriology to the sanitarian in forming a judgment of the quality and potability of such water?

A. The data derived from bacteriology and chemistry are often the only data that a sanitarian has for forming a judgment as to the character of a given water. Correctly interpreted these data afford very valuable and significant clues as to the sanitary history of a water and often to its quality at the time the examination is made. For a full and complete understanding of the character of a water such chemical and bacterological examinations are indispensable.

Q. From all the tables and analyses submitted by you in evidence in this case, where is the locality along the Illinois river where practical purification of the sewage of Chicago has taken place?

A. Assuming that by practical purification is meant the death of typhoid bacilli, in my opinion this purification has occurred before the flow of the Illinois river reaches Avery-
10172 vile. The exact point must vary somewhat with rate of flow, temperature, number of bacilli introduced, concentration of sewage, etc.

Q. Has the question of self-purification of running streams received consideration from scientific men?

A. Yes, sir, the question of self-purification of running streams has often been broached and great attention has been given to the problem in Europe and in parts of this country.

Q. Are you acquainted with the views of scientific men expressed upon this subject?

A. I have read the statements on this matter in the leading authorities on water supply and river water published in English, French and German.

Q. What statements are there regarding the process of self-purification, regarding running waters?

A. I have here a quotation from a book entitled "Water and Water Supplies" by Dr. John C. Thresh, Medical Officer of Health to the Essex County Council; Lecturer on Public Health, King's College, London; Editor of the Journal of State Medicine; Hon. Sec. Incorporated Society Medical Officers of Health; Fellow of the Institute of Chemistry; Member of the Society of Public Analysts, etc.

This book is one of the best known and most authoritative treatises in the English language on water supply. 10173

The statement follows:

"The balance of evidence is decidedly on the side of those who uphold the theory of self-purification, and the diverse conclusions arrived at by different observers can be accounted for by the varied and often imperfect character of the experiments, and by the diverse conditions which obtain in different streams. That river water, grossly befouled by sewage in its higher reaches, becomes a few miles lower down so pure, from a chemical point of view, as to be certified by the most eminent analysis to be fitted for all domestic purposes, and is actually so used by millions of our population, is a fact which can not be gainsaid. Whether this process of purification be merely due to sedimentation and dilution, or to those factors, assisted by oxidation, is however, a matter of trifling importance, since it is now fully recognized that the disease producing material is not the dead organic matter in solution, but the living organisms in suspension. The problem is not a chemical one, but a biological one."

The statement above is made by Dr. Thresh in his chapter on the self-purification of streams.

In my opinion this statement in Dr. Thresh's treatise represents correctly the prevailing opinion today among 10174 students of this question. Similar statements appear in other English and in German treatises.

Q. In order to qualify as a sanitary expert is it necessary for such expert to have a knowledge of chemistry and bacteriology?

A. I should consider that some knowledge of chemistry and bacteriology was absolutely necessary for the fundamental principles of sanitary science.

Q. Does not a sanitary expert call to his assistance all the information available from chemistry and bacteriology as well as knowledge of the sources of pollution in passing judgment on the sanitary character of a river?

A. It seems to me self evident that all information of whatever kind that tends to shed any light on the questions at issue should be considered by an epidemiologist in the course of his investigations.

Q. As a sanitary expert, acquainting yourself with all the means of bacterial knowledge which is available to you, what is your opinion as to whether a typhoid bacillus lying in the sediment of a polluted stream for a period of sixty days would be able to cause typhoid when taken in the human system after it had remained in such sediment for that length of time?

10175 A. It is my opinion that a typhoid bacillus that had remained alive for sixty days in the sediment of a stream or a lake,—a supposition in itself extremely improbable,—would not be virulent and capable of causing disease in man. I base this opinion upon the observations on virulence of typhoid bacilli after a long sojourn in water. Meager as these observations are, they indicate that a decline in virulence does occur. I should like to add that from all the information that I have been able to gather it seems to me highly unlikely that a typhoid bacillus could remain alive and virulent in sediment for a period as long as that designated.

Q. What is your opinion as a sanitary expert as to whether polluted or infected matter coming from the sewers of Chicago through the drainage canal, deposited on the bottom of the Desplaines and Illinois Rivers, between Chicago and Peoria, can remain there for a period of from thirty to sixty days and yet contain dangerous matter as well as pathogenic bacteria?

A. As I understand the question the terms "dangerous matter" and "pathogenic bacteria" mean one and the same thing, since the so called dangerous matters present in ordinary sewage may for practical purposes be taken to mean
10176 pathogenic bacteria. As I have already stated I do not
believe that the typhoid bacillus, which is the only one of the pathogenic bacteria that need be considered in this con-

nection, may retain its virulence under the conditions designated.

Q. From your personal knowledge of the Illinois River and your knowledge as a sanitary expert, together with all chemical and bacterial knowledge derived from every source, what is your opinion as to whether the sewage from the City of Chicago, passing through the drainage canal into the Illinois River in the different seasons of the year, and at different stages of the water in the Illinois River would be a danger and menace to the inhabitants of the State of Missouri and the citizens of the city of St. Louis using the water at the intake tower at the chain of rocks, or from the Mississippi River as the same passes along the eastern shore of the State of Missouri?

A. From a long and searching examination of all data, chemical, bacteriological and epidemiological from every source, that I have been able to secure, I am convinced that the citizens of the city of St. Louis and the inhabitants of the State of Missouri are not menaced by or endangered by infectious materials passing into the sewers of Chicago and thence into the
10177 drainage canal.

Q. What is your opinion as a sanitary expert, based upon all the tables of your chemical and bacterial analysis, introduced in evidence, of the waters of the Illinois, Mississippi and Missouri Rivers as represented by such tables, as to which one of these three rivers, from these analyses, discloses the least amount of impurity or pollution?

A. Comparing the Missouri River near its mouth with the Illinois River above Grafton, and the Mississippi River above Grafton, I have no hesitation in saying that I regard the waters of the Mississippi and Illinois, at the point indicated, less dangerous and less unwholesome than the waters of the Missouri River. Between the Illinois and the Mississippi Rivers, at the point indicated, there is, in my opinion, not much to choose from a sanitary point of view.

Q. If the Illinois and Mississippi Rivers disclose from such data as aforesaid the least amount of impurity, what would be the effect of the waters of the Illinois River emptying into the Mississippi River at Grafton and consequently uniting with the Missouri River at its mouth, upon the combined waters of the Mississippi, Missouri and Illinois River at the intake tower and chain of rocks?

A. Such an admixture as occurred of the Illinois River water with the Missouri River water would tend to improve the
quality of the water since the number of colon bacilli
10178 in the waters of the Missouri River are distinctly greater
than those in the waters of the Illinois, and this condition, in my opinion indicates that the Missouri River water, which is more highly charged with these objectionable bacteria, is more likely to be the vehicle of typhoid fever bacilli than the water of the Illinois which does not contain so many bacteria of this type.

Q. Does the mixing of the Illinois with the Mississippi and Missouri Rivers, as indicated in the foregoing question, create any added danger to the already polluted and contaminated waters of the Missouri and Mississippi Rivers below Grafton?

A. In my opinion it does not.

Q. From all your knowledge of conditions that obtain in and below the Illinois River, what is your opinion as a sanitary expert as to whether deleterious substances, infectious matter or pathogenic germs which come from the drainage canal, from the sewers of Chicago, would reach as far down the Illinois River as the city of Grafton?

A. All the analytical data that I have obtained myself and all that I have seen which has been obtained by other investigators indicate both from the chemical changes that take place
and from the diminution in the number of ordinary sewage
10179 bacteria, and especially in the diminution of the number of
bacillus coli communis that under existing conditions, infectious materials introduced into the sewers of Chicago can not and do not pass down the Illinois River as far as Grafton.

Q. Do any of these substances in a dangerous state, reach the intake tower of the St. Louis water works at the chain of rocks in your opinion?

A. In my opinion they do not.

ADJOURNED UNTIL 2:00 P. M., SAME DAY.

10180 2:00 P. M., Thursday, February 11, 1904. Continuation pursuant to adjournment. Present, the Commissioner and same counsel representing the respective parties.

PROF. EDWIN O. JORDAN

resumed the stand for further direct examination by Mr. Todd, and testified as follows:

Q. Assume that in 1890 the increase in typhoid fever in Washington, D. C. was due to an epidemic of typhoid fever in Cumberland, Maryland, and assume that Cumberland, Maryland, is 580 feet above the level of Washington, D. C., and is distant by water 170 miles, or in time 4 days. Assume the above facts to be true, does the typhoid condition in Washington and Cumberland afford any epidemiological or sanitarian basis for a comparison between those cities and the city of St. Louis and Chicago, taking into consideration that the elevation of Chicago over St. Louis is approximately 198 feet and distance 357 miles, or 18 1-2 days the mean average time of flow, together
10181 with all that you know about existing conditions that obtain upon and in the water courses between Chicago and St. Louis?

A. On the assumption just stated it would certainly be impossible to draw a fair comparison between the conditions prevailing on the water sheds of the Illinois and Potomac Rivers. The relatively very rapid flow from Cumberland to Washington and the relatively short space of time within which a body of water can travel this distance represents a very different set of conditions from those prevailing in the Illinois River between Chicago and St. Louis, since in the lower portion of the Illinois River the current is sluggish and the time required for a body of water to pass a mean average flow from Chicago to St. Louis is very much greater than the required time, on the assumption, to pass from Cumberland to Washington. The conditions are, therefore, radically different and it does not follow that if typhoid bacilli have passed from Cumberland to Washington, under the conditions prevailing on that watershed, that typhoid bacilli can also pass from Chicago to St. Louis under the conditions prevailing in the Desplaines, Illinois and Mississippi Rivers.

Q. As a sanitary expert do you consider the sewage of
10182 Chicago entering the drainage canal, the Illinois River,
which in turn enters into the Mississippi River, a menace and a danger to the inhabitants of the State of Missouri and to the citizens of the City of St. Louis, taking their water supply from the Mississippi River and from the intake tower at the chain of rocks from the Mississippi River?

A. I can not regard the discharge of sewage into the Chicago sewers and into the drainage canal under the conditions specified as constituting any danger in the way mentioned to the health of the citizens of St. Louis and the inhabitants of the State of Missouri. In my opinion the dangerous elements in Chicago sewage are eliminated from the Illinois River before the mouth of said river is reached.

Q. What is your opinion as a sanitarian expert as to whether the germ of typhoid fever could lie in the sediment of the drainage canal or upon the bottom of the Illinois River for a period of from one to three years?

A. It is my opinion that the typhoid bacillus could not live nearly as long as from one to three years in the sediment of the river or drainage canal.

Q. Do you know of any instance on record or reference in literature upon the subject of bacteriology where the ty-
10183 phoid bacillus has lived from one to three years in the
sediment of streams?

A. I know of no such case.

Q. What is your opinion as to whether a typhoid bacillus deposited on the bottom of the Illinois River could remain there for a period upwards of five years and then be stirred up by the action of the waves, winds, steamboats or by other means, could continue its journey down to St. Louis in a virile state and be a cause of danger to the inhabitants of the State of Missouri using the water of the Mississippi River and to the inhabitants of the City of St. Louis using the water of the Mississippi River for drinking purposes?

A. The hypothetical case proposed in your question of a typhoid bacillus living as long as five years in the sediment of the Illinois River and retaining its virulence during that period is, so far as I am aware, wholly without basis in observed fact and finds no support in the deductions that can be drawn from my own observations or from the observations of others upon the conditions prevailing in the Illinois River or elsewhere.

Q. What is your opinion as an expert chemist, and bacteriologist, as to whether the pollution and contamination
10184 from the sewers of Chicago, emptying into the Chicago River and thence into the drainage canal, continues to be manifest and persistent as far down the Illinois River as Grafton and at the chain of rocks on the Mississippi River?

A. The pollution that has occurred at Chicago is manifest at the mouth of the Illinois River chiefly in the increased amount of chlorine present in the water of the Illinois River at that point. The introduction of a large amount of nitrogenous organic matter is also betrayed by the large amounts of various compounds containing nitrogen present in the water of the Illinois River at its mouth, but so far as the original polluting matters and pathogenic bacteria introduced into the Chicago drainage canal are concerned, I can find no grounds for adopting the opinion that these substances and these bacteria persist in their original condition as far down the river as Grafton.

Q. From your examination of the waters of the Illinois River what is your opinion as a sanitary expert as to whether any of the original organic matter of the sewage from Chicago finds its way into the intake tower of the St. Louis water works at the chain of rocks?

A. It seems to me quite possible that some of the very stable and slightly oxidizable compounds introduced into the sewage of Chicago may reach the mouth of the Illinois
10185 River but these stable compounds which do not undergo ready decomposition under natural conditions have, so far as is known, no sanitary significance. The unstable and readily oxidizable nitrogenous products are, in my opinion, altered before reaching the mouth of the river to such a degree that it can not be properly said that any of the original organic matter finds it way to the intake tower of the St. Louis water works.

Q. Will you state your opinion as a sanitary expert, basing your opinion on all the information you possess in this case, whether the water supply of St. Louis is contaminated, polluted or injured by the sewage of Chicago entering the drainage canal and from thence into the Illinois River?

A. It is my firm opinion that no such pollution, contamination or infection of the St. Louis water supply, by the sewage of Chicago, occurs.

Mr. Jeffries: I object to the question unless the witness confines his answer to the information which he may have regarding conditions affecting the sanitary condition of the water of the Illinois and Mississippi River as has been detailed by him in his evidence and as is shown by his testimony.

Q. What effect does an increased volume of water in the Illinois River have upon the low lands lying along the 10186 banks of the Illinois River?

A. At such high water periods the low lands along the banks of the Illinois River, especially in its lower stretches, are flooded and large stretches of the river become for days immense settling basins.

Q. If the increased water at flood times from the tributaries of the Illinois as well as the Illinois itself, exclusive of the water of the drainage canal, causes a large area of the land to be overflowed along the Illinois river valley, what effect does this overflow have upon sedimentation of the sewage from Chicago entering the Illinois river through said canal?

A. So far as the current of the river is slackened in these overflowed areas, so far will those elements in the sewage that persist long enough to reach these points be retarded in their passage down the river and perhaps be permanently deposited on these flooded low lands.

Q. What would be the effect upon sedimentation if the volume of water was great, thereby causing a greater area of territory to be overflowed in the Illinois river valley?

A. The larger the amount of territory flooded the greater will be the opportunities for sedimentation of particles, and retarding the flow.

Q. Assume that five dams, one at Marseilles, one at Henry, one at Copperas Creek, one at La Grange and one at 10187 Kampsville, exist in the Illinois river, backing the water up stream for a considerable distance; also there is a lake known as Lake Joliet, a lake above Peoria known as Lake Peoria and many small lakes lying along the Illinois river, receiving their water supply from the Illinois river, what effect do these dams and lakes have as sedimentation basins and also what effect do they have in the elimination and purification of polluted and infected matter, coming into the Illinois river from the Chicago drainage canal?

MR. JEFFRIES: Objected to for the reason that the defendants' testimony shows, and the examination of the witnesses along the Illinois river, that since the opening of the drainage canal there has been and is now a continuous direct and ever flowing current in the Illinois river, from source to mouth, and while it may be true that certain lakes obtain in part their supply of water from the Illinois river, yet the fact remains that the current is often continuous and direct from the source of said river to its mouth, and that the facilities for sedimentation, as elicited by the question, are not affected by or in any way material to the question here involved.

10188 A. These dams and slack water basins or lakes in my opinion materially facilitate process of sedimentation and also serve to retard the current in a not inconsiderable degree.

MR. JEFFRIES: I move to strike out the question and answer for the same reason stated in my objection to the question and for the further reason that defendants' testimony shows that so far as the dams on the Illinois river that were constructed by the State of Illinois, they not being kept in proper condition an effort is being made to have such dams remvoed because the opening of the drainage canal has removed the reason for their construction, and for the reason that the State of Missouri has no assurance upon the part of the Federal Government or of the defendants herein that any of the dams so constructed will be continuously maintained from now on, even though it be conceded that they play an important part in effecting the purification of the sewage from the City of Chicago, and for the further reason that the evidence here shows since the opening of the drainage canal a continuous and ever-flowing current, from one end of the year to the other, both above, below and over said dams, thereby removing the facilities for sedimentation and such purification as necessarily was produced ther[illegible] prior to the opening of said canal when the water immediately and for miles above the dams remained

10189 in practically a quiescent state during the greater part of the year, such conditions as then existed not pertaining to said river on account of said dams since the opening of said canal.

Q. Assuming that the dams at Henry, Copperas Creek, LaGrange and Kampsville, as they exist today, should be removed from the Illinois river, what effect would the removal of these dams from the Illinois river have upon the water supply of the State of Missouri and the City of St. Louis assuming that the sewage from Chicago should enter the drainage canal and thence into the Desplaines and Illinois rivers after the dams were so removed the same as it does under present conditions?

MR. JEFFRIES: Object to the question for the reason that the questions heretofore put by the counsel for defendant assume and take it for granted that said dams to a certain extent are a means of purification and to such an extent a safe guard to the people of the State of Missouri, and for the further reason that it is incompetent, irrelevant and immaterial.

A. So far as the purification of the sewage of Chicago is concerned the assumption of the removal of the dams at the places stated would in my opinion not materially affect such purification, since the elimination of typhoid bacilli takes place, in my judgment, in the upper stretches of the Illinois
10190 river. It is possible that a removal of said dams might have some effect in retarding the purification of the sewage and the elimination of dangerous bacteria discharged by various communities in the lower half of the river.

Q. Would the water supply of St. Louis at the St. Louis intake and the citizens of Missouri taking their water supply from the Mississippi river be endangered or infected by the sewage of Chicago entering the drainage canal if the four dams before mentioned in the Illinois river should be removed?

A. Not so far as the danger of infection in the sewage of Chicago is concerned.

Q. From your chemical and bacterial examinations what parts do the dams in the Illinois river play in the purification of the sewage from Chicago?

A. In my opinion they have little, if any, share in effecting or accelerating the purification of the Chicago sewage.

Q. Will you state as an expert sanitarian and epidemiologist from all sources of knowledge that you possess whether the water of the Mississippi river at the chain of rocks was prior to January, 1900, a safe and potable drinking water fitted for domestic and drinking purposes in its raw state?

10191 A. In my opinion the Mississippi river water at the intake tower at the St. Louis water works at the chain of rocks was unfit and unsafe for drinking purposes during the period mentioned.

Q. Was the Missouri river at Ft. Bellefontaine a safe water for drinking and domestic purposes in its raw state or treated with settling basins prior to the opening of the drainage canal in January, 1900.

MR. JEFFRIES: All these questions are objected to as being immaterial.

A. Assuming that the period of storage of such water in settling basins was not greater than three or four days it is my opinion that such water was not fit or safe.

Q. Was the Illinois River water a safe water for drinking and domestic purposes prior to the opening of the drainage canal in January, 1900, at Grafton?

A. In my opinion it was not.

Q. Has the sanitary condition of the water of the Illinois River at Grafton been improved or damaged by the opening of the drainage canal?

A. In my best judgment the sanitary quality has not been materially affected either in the direction of improvement or in deterioration.

10192 Q. Since the opening of the drainage canal are the waters of the Illinois River at Grafton less sanitary than the waters of the Missouri River at its mouth or the Mississippi River above Grafton?

Mr. Jeffries: I object to the question as immaterial.

A. So far as I can judge from all the analytical data that have come under my observation the Illinois River water at this time was no worse than the water of the Mississippi River, while the water of the Missouri River was distinctly inferior in its sanitary qualities to both the water of the Mississippi and the Illinois.

Q. What effect does the sewage discharged through the drainage canal have upon the waters of the Mississippi River and the Missouri River at the chain of rocks?

Mr. Jeffries: I object to the question as immaterial and a repetition.

A. Beyond increasing the amount of chlorine and perhaps of some other constituents of no sanitary significance it is my opinion that the sewage of Chicago has had no material effect upon the water of the Mississippi River as indicated in the question.

Q. Does the sewage of Chicago, in your opinion, even reach the intake tower of the city of St. Louis at the chain of rocks?

A. If by sewage is meant living pathogenic bacteria I
10193 am firmly of the opinion that it does not. If by sewage
is meant the original, unstable organic compounds of Chicago sewage I am also of the opinion that these do not reach the chain of rocks, at any rate in any quantity possessed of sanitary significance.

Q. Are the waters of the Mississippi and Missouri Rivers, exclusive of the water of the Illinois, safe and suitable water for domestic and drinking purposes, to be used by the citizens of St. Louis in its raw state or treated as now by the City of St. Louis in settling basins?

Mr. Jeffries: I object to the question as immaterial.

A. In my opinion the water of the Missouri River at its mouth and the water of the Mississippi River at the chain of rocks excluding the Illinois River from the latter, are not fit and wholesome waters and would not properly be recommended as a source of municipal water supply in a raw condition.

Q. If the sewage from Peoria and all other towns along the Illinois River and its tributaries as well as the rural population upon the water shed of the Illinois River was eliminated from the Illinois River would all of the sewage of Chicago be eliminated long before it reached Grafton.

10194 Mr. Jeffries: I object to the question as leading.

A. In my opinion it would, so far as the ordinary decomposable and unstable organic substances are concerned. It would also disappear so far as the pathogenic bacteria originally present in said sewage are concerned.

Q. If the typhoid condition in St. Louis since 1900 can not be attributed to the sewage from Chicago beyond a reasonable doubt will you please state what cause in your opinion it should be attributed to and give your reasons for such an opinion?

A. Assumning that the amount of typhoid fever occurring in St. Louis during the period mentioned is in excess of what would naturally exist in a city provided with a fairly pure and satisfactory municipal water supply in my opinion the most rational and scientific explanation of such excess would lie in the infection of the Illinois, Mississippi and Missouri Rivers above the intake tower of the St. Louis water works by communities rural and urban within five or six days flow from the intake tower. Since in my opinion the major part of the water supplied to St. Louis during this period was derived from the Missouri River and inasmuch as it is my opinion the Missouri River is more seriously infected than either of the other rivers mentioned it is my judgment that the infection of the Missouri River has been the main factor in causing such excess of typhoid fever in St. Louis as occurred during the period under consideration. 10195

Q. Professor, taking into consideration all the knowledge which you possess in regard to the chemical, bacterial and physical condition of the waters of the Illinois River and its tributaries; the different towns sewering into the Illinois River and into its tributaries; the population upon the water sheds of the Illinois River, both rural and urban; the stages of the river under all conditions and during all seasons, what is your opinion as a sanitary expert as to the effect of flowing the sewage from Chicago through the drainage canal into the Desplaines and Illinois River upon the inhabitants of the State of Missouri using the waters of the Mississippi River for drinking and domestic purposes?

A. It is my opinion, assigning due consideration to all the facts mentioned, that the discharge of the sewage of Chicago into the drainage canal has had no injurious or detrimental effect upon the health of the inhabitants of St. Louis or the State of Missouri.

Q. Professor, taking into consideration all the knowledge which you possess in regard to the chemical and bacterial and physical condition of the waters of the Illinois, the Mississippi

and Missouri Rivers and their tributaries; the different towns sewering into these three rivers and their tributaries, the
10196 population upon the watersheds of these three rivers, both rural and urban; the stages of the three rivers under all conditions and during all seasons and taking into consideration all the knowledge that you have in regard to the typhoid conditions as they obtain along the water shed of the Missouri and Mississippi and Illinois Rivers, in the City of Chicago and in the City of St. Louis, what is your opinion as to whether the typhoid conditions as they have existed in St. Louis, since January 17, 1900, the date of the opening of the drainage canal, can be attributed to the opening of the drainage canal as the direct, immediate and proximate cause of said typhoid condition existing in said City of St. Louis beyond all reasonable doubt?

A. Summing up all the experience that I have gained in my studies of the Illinois and Mississippi and Missouri Rivers and their tributaries and all the information that I have gained from all sources it is my firm opinion that no relation near or remote, has been traced between the typhoid conditions in St. Louis since January 17, 1900, and the opening of the drainage canal on that date; and it is further my opinion that no such relation exists, and that the opening of the drainage canal was an event entirely unconnected and unrelated with any typhoidal conditions prevailing in St. Louis at that time, and has
10197 remained up to the present time, unrelated and unconnected with the typhoid fever mortality in the City of St. Louis.

Adjourned until 10:00 a. m., February 12, 1904.

10198 10:00 a. m., Friday, February 12, 1904. Continuation pursuant to adjournment.

Present, the Commissioner and same counsel representing the respective parties.

PROF. EDWIN O. JORDAN

resumed the stand for cross-examination by Mr. Jeffries, and testified as follows:

Q. Professor, have you ever examined water known to be infected with typhoid germs, that was used or being used for domestic and drinking purposes?

A. I am not sure what is meant by the expression "known to be infected with typhoid germs." If by that expression is meant a water which there was reason to suppose was causing on excessive amount of typhoid fever among the community served with such a supply, I would say that I have examined such waters. If by the expression is meant that typhoid germs were known to be in the samples of water at the time the examination was made, I would say that I have not. A given source of supply, as a lake or a river, may, on epidemiological grounds, be suspected of causing typhoid fever, but when an examination of such water is made the typhoid bacilli may have disappeared. It is chiefly for this reason, in my opinion, that the findings of typhoid bacilli are so few in number.

10199 Q. Then I understand you to say, Professor, that you have not examined water known to be infected with typhoid fever germs at the time of the examination, which water was being used or had been used for drinking purposes and domestic purposes?

A. I have never found typhoid bacilli in such water.

Q. But have you made an examination of such water?

A. As stated in my first answer the only proof that such water was infected with typhoid bacilli at the time an examination was made would be the finding of such bacilli in the water. This I have never accomplished.

Q. Then do I understand you to say that there can be no other proof of the existence of typhoid fever germs in water other than the absolute finding of them by the analysis in the water?

A. No sir, that is not a correct inference. The presence of typhoid fever germs in a water might be demonstrated either by finding them in such water or it might be demonstrated by administering such water to a healthy human individual under laboratory conditions, excluding all other sources of infection. These are the only methods I know by which the existence of typhoid bacilli in a given quantity of water could be determined beyond a question.

10200 Q. What is the most general way in which typhoid infected water has been so determined in the scientific world?

A. I know of no royal road to the accomplishment of this end. The question of the sanitary quality of a water can be approached in other ways and by other methods than by a direct search for the presence of a typhoid bacillus in a given quantity of water.

Answering your question directly I would say that in my opinion the most convincing evidence of the presence of typhoid bacilli in a given water during a given period would be the tracing of cases of typhoid fever to that water, it being assumed that other sources of infection were sufficiently well excluded to permit the establishment of the conviction that the particular water under consideration at the particular time stated was responsible for the production of the cases of typhoid fever.

Q. Then, as I understand you, the best evidence as to water being typhoid infected is the result which it produces upon a community using it for domestic and drinking purposes? Is that true?

A. That is true.

Q. Now, Professor, have you, during the pendency of a typhoid epidemic, which was reasonably known to have been caused by the use of a certain water supply examined 10201 that water supply scientifically, chemically and bacteriologically?

A. The long period of incubation in typhoid fever—about 14 days—and the period that elapses before death occurs—an average perhaps of about three weeks—brings it about that at least several weeks elapse between infection with typhoid fever bacilli and the first manifestations of the existence of an epidemic. For this reason examination of the water in such epidemics is not, as a rule, made until after infection has taken place. During this period of four or five weeks elapsing between infection and bacteriological examination the conditions of the water may become so altered that it is no longer infectious. I have made some examinations of water supplies while the epidemic itself was pending, but in all such cases a considerable interval had elapsed since the initial infection that gave rise to the epidemic.

Q. State briefly what water supplies were examined by you as mentioned in your last answer?

A. I made some examinations of the water supply of the city of Chicago in the fall of 1902. I also, a number of years ago, made examinations of the water supply of the city of Lowell, at the time a typhoid epidemic was prevailing there. There was reason in both these cases to think that the water supply was the cause of the outbreak of typhoid fever prevailing in these respective communities. 10202

Q. Did you make any examination of the water supply at Butler, Pa., and Ithaca, New York?

A. No, I did not.

Q. How long in your opinion did this infection at the places mentioned by you continue?

A. At Lowell there seems to have been infection of the water supply by several cases of typhoid fever on several occasions. I do not recall the exact dates on which such infection occurred nor do I know that such exact information was obtainable. I have no means of knowing the period through which infection lasted at Chicago.

Q. Have you any information as to the duration of the infection in the water supply at Ithaca, which you have testified to in your direct examination?

A. I have not.

Q. Do you know how long the epidemic had prevailed prior to your visiting Ithaca, New York?

A. So far as the facts could be ascertained regarding the time of onset and the outbreak it appears that about 14 cases of a low fever, possibly typhoid, occurred between November 17, 1902, and January 15, 1903. Then on January 15, some 5 or 6 cases of fever developed and during the following week several cases each day were reported. After January 25th the number of cases reported daily seems to have increased very materially, and the presence of a serious epidemic began to be recognized. 10203

Q. When did you say you visited Ithaca?

A. I reached Ithaca on March 7th and remained there about a week.

Q. Were there any cases of typhoid fever in Ithaca at the time you were there?

A. There were a great many; several hundred.

Q. Were there any new cases developed while you were here?

A. Yes. Cases continue to develop in every large epidemic f typhoid fever long after the original source of infection has isappeared. This is what is known as secondary infection, hich plays an important part in the spread of every considerble epidemic. This source of infection was very conspicuous oth at Ithaca and at Butler.

Q. In what way did this secondary infection manifest itelf at Ithaca?

A. Cases of typhoid fever occurred in the household of atients already sick with the disease, among the family or mong the nurses, physicians or attendants on the sick. This o-called secondary infection consists in a more or less direct transfer of bacilli from the body of the patients to those
0204 persons in the immediate surroundings of the patient.

Professor Sedgwick has called attention to a very interestng instance of secondary infection in Bondville, Massachusetts.

Q. This secondary infection that you speak of is attribuable to the association of persons with those having typhoid ever is it?

A. Yes sir, that is what is generally meant by secondary nfection.

Q. As a matter of fact, Professor, were there not newly eveloped cases of typhoid fever at Ithaca when you were there, ttributable to the primary infection or cause?

A. I think that that is quite possible. The history of infection of the water supply, so far as it could be gotten at, ndicates that bacilli had been washed from the soil or from acumulations on the banks of the stream in Six Mile Creek which erved as a source of the supply. If any such fountain head of nfection existed, it might continue to be active for a long eriod, owing to the circumstance, which I have already menioned on several occasions, that typhoid bacilli can live for eeks or even months in such accumulations of fecal matter or in soil so that the water supply of Six Mile Creek may
10205 have been fed for a considerable period with typhoid bacilli.

Q. Can you describe the reservoir which contains the water supply or holds the water supply of Ithaca, as it existed at that time?

A. The water supply of the city of Ithaca was considerably mixed. A mixture of the water from the Six Mile Creek and Buttermilk Creek was pumped into a small reservoir, holding, if I remember correctly, hardly more than a day and a half's supply.

Q. Do you know anything as to the depth of the water in that reservoir, and its dimensions, its length and breadth?

A. I have no precise memoranda on those points with me at present. I obtained them at the time I was in Ithaca, but have not them with me at present.

Q. If the first noticeable cases of typhoid fever appeared in Ithaca about the 17th of November, 1902, in your judgment how long prior thereto was the water supply of Ithaca infected with typhoid bacilli?

A. In my opinion the water supply of Ithaca had probably been infected with typhoid bacilli at intervals for some years prior to this date. The previous history of the typhoid fever and the so-called Ithaca fever in the town indicates that the water supply had been more or less infected for some 10206 years. The prevailing opinion among persons connected with Cornell University and who paid attention to matters of this character was that the water supply had been unsafe for such a considerable period, and in many families it had not been used in its raw condition for years before this specific outbreak of typhoid fever. From the best information that I could obtain there seems to have been a certain amount of typhoid fever on the water shed of Six Mile Creek at intervals during a very long time.

Q. With reference to the specific epidemic at Ithaca, which you investigated, how long prior to November 17th was the water supply of that city infected to an abnormal extent, so as to produce and bring about the epidemic at that place?

A. I should not place the outbreak of the epidemic at Ithaca quite as early as November 17th, since there were only 14 cases between November 17 and January 15th. The specific outbreak of typhoid fever at Ithaca seems to have begun about January 15th. The specially heavy infection which gave rise

excessive number of typhoid fever cases appearing on
te may have occurred between 10 and 18 days previously.

Is it not a fact that there had been no cases of typhoid
n the water shed of Six Mile Creek for several weeks
o the outbreak of the epidemic at Ithaca?

A. The exact source of this epidemic has, in my opinion,
not been definitely ascertained, that, is the precise
case or cases of typhoid fever that gave rise to the ex-
ly heavy pollution of the water of Six Mile Creek. Two
e sources of infection were, however, quite conspicuous
ninds of persons in Ithaca. One of these was the presence
e Italian laborers some months previously who had en-
l along the banks of Six Mile Creek during the process
tructing a dam, and the other was the presence of some
y laborers constructing a culvert over the stream. No
of typhoid among the Italian laborers could be obtained.
ling the railway workmen the case was somewhat more
ous. Whatever the source of infection, however, it seems
have been a case of direct water pollution, but a washing
f bacilli from the soil or from fecal accumulations.

Is it not a fact that an effort was made in investigating
al homes upon that water shed and in that investigation
s of typhoid fever were found in those homes for several
prior to this epidemic?

I believe that Dr. Soper, representative of the New
State Board of Health, was conducting such investigation
ime of my visit in Ithaca. I have not seen any published
ent of the outcome of this inquiry.

Q. Was not an investigation of this character going on
at the time you were there?

A. Yes sir. That is the one I referred to as being con-
under the supervision of Dr. Soper.

In the event bacterial analysis had been made at the
at any time within thirty days prior to the epidemic, in
dgment would any such analysis disclose the presence of
l bacilli?

I think that is possible.

Is it probable?

That would depend upon several factors. First, the number of typhoid bacilli in the water; second, the methods used for examination of the water; third, the extent of the examination.

Q. In the event there be one typhoid fever germ for every pint of water, would you consider that as a water supply highly infected or not?

A. I should not.

Q. And such an infection would not, in your opinion create or cause a typhoid fever epidemic?

A. Nothing is known as to the number of typhoid fever bacilli necessary to produce a case of typhoid fever in man.

10209 Q. Based upon your last answer how then can you say that a distribution of typhoid fever germs in the water supply at the ratio of one germ for each pint of water is not to be considered a highly infected water?

A. While nothing definite is known as to the number of typhoid bacilli necessary to produce a case of typhoid fever in man, some light is thrown on this by experiments made upon animals. It is well known that in working experimentally with pathogenic microbes a single germ is rarely able to produce infection. Based upon laboratory experiments with pathogenic bacteria it is my opinion that a single typhoid bacillus would not be capable of causing an infection in a human being, since it is found that in practically all cases of inoculation of animals with specific pathogenic bacteria, not one germ alone but many hundreds must be used in order to produce infection, even when these bacteria are introduced into the most delicate portions of the body.

As indirectly bearing on your question I may mention a case which has recently been published of the attempted suicide by a laboratory worker through swallowing typhoid cultures. Several tubes of broth cultures of typhoid bacilli were swallowed with the aim of committing suicide, but only a

10210 mild case of typhoid fever resulted in spite of the hundreds of millions of bacilli that were taken in in this highly infected broth. It is of course a matter of opinion as to what constitutes a highly infectious water. Personally I should not gard a water containing one typhoid bacillus per pint as a ghly infected water.

Q. This instance of experimental suicide would not in your inion have the same effect if undergone by all persons pro- scuously would it?

A. Certainly not.

Q. So then certain typhoid infected water may be a high ection as applied to certain persons or when taken into the stem by certain persons, when it would not be highly infected en taken into the system by other persons? Is that true?

A. On that point again there is very little data on which to se an opinion. We do not know how widely the susceptibility different individuals in infection with typhoid fever bacillus ries or upon which such susceptibility depends. Individuals tween the ages of 15 and 35 are, as is well known, more liable typhoid fever than younger persons or those of more ad- vanced age, and it is a striking and well recognized fact
211 that robust individuals in apparently excellent physical
condition contract cases of typhoid fever when weaker lividuals do not. Upon what this variation and susceptibility pends, or how great it is, there is, as I have said little informa- n. There are certainly individual differences in respect to ection with typhoid fever just as in the case of other diseases.

Q. What do you understand to be highly infected typhoid ter as applied to sanitary science and to the history of epi- mics with which you are acquainted.

A. I should regard the water supply of Ithaca and Butler the time of the typhoid epidemics pervailing there as a ghly infected water. In these two communities almost ten r cent. of the population was affected.

Q. Is there anything in sanitary science that enables one reach the conclusion that the water supply of either Ithaca Butler was infected to a greater extent than one typhoid rm to each pint of water contained in those suppplies?

A. Only the reasons which I have given, which seem to me fficient.

Q. Is there anything in the science which furnishes absolute d definite assurances that an infection of one typhoid germ one pint of water, when contained in the water supply of a

10212 city such as Ithaca or Butler will not, does not and has not produced typhoid epidemics in those cities?

A. I have aready expressed my opinion that all the experience gained in bacterioligical laboratories from inoculation of hundreds and thousands of animals with many kinds of pathogenic bacteria, under varying conditions has shown that rarely if ever can one germ or two or three germs, even when belonging to highly virulent varieties, produce an infection. So far as I know, this analogy is all that we have to depend upon for forming an opinion on the point indicated in your question.

It is my opinion that swallowing one or two or a half dozen typhoid germs would not produce a case of typhoid fever in man, basing this opinion on the analogies drawn from laboratory experience.

Q. As an epidemiologist will you make any alterations in the conclusions which you have just drawn?

A. If it could be shown by indisputable proof that a community supplied with a water supply containing not more than one typhoid germ per pint of water developed a largely excessive amount of typhoid fever, plainly attributable to the use of such water, I should certainly change my opinion.

Q. This answer then is based upon the fact that there is no way of determinig scientifically or otherwise the cause 10213 of the infection of any water so far as the quantitative infection is concerned is it not?

A. It is based rather upon the fact that we do not know how many typhoid bacilli are necessary to produce a case of typhoid fever in man.

Q. Typhoid fever is contracted by drinking water is it not, professor?

A. That is one of the ways in which it may be contracted.

Q. Is that the most prevalent and general way?

A. Taking the world as a whole I think it is undoubtedly.

Q. While it may be true as stated in your second preceding answer that it has not yet been scintifically determined as to the exact number of typhoid germs necessary to produce typhoid fever in a patient is it not also true that science has thus far been unable to determine quantitatively speaking the extent of the infection of the water known to be infected?

A. Understanding that question to mean the number of yphoid bacilli present in the water at the time that the use of uch water has given rise to an epidemic of typhoid fever I vould say that so far as I am aware the number of typhoid acilli present in such water has never been precisely deternined.

Q. Do you know of any instance where the typhoid fever
0214 germ has been discovered by bacteriologists in their analysis of the water supply of the city?

A. Yes, I have already submitted in my testimony a record f all the cases that I have been able to find in the literature on he subject where a typhoid bacillus has been isolated from water upplies.

Q. And the cases to which you refer are known by you as he six recorded cases?

A. They are, I know of only the six cases that I have reerred to.

Q. And those six cases are the result so far as you know f the work of bacteriologists as applied to the sanitary science or a number of years past, is it not?

A. I should not be willing to make any such a broad statenent. I should simply confine myself to the statement I have lready made that these are the only recorded instances I have een able to find in the literature where the typhoid bacillus as been discovered in water ordinarily used for drinking. The ime that elapses after the infection of water before a cometent bacteriological investigation can be set on foot is one eason why bacteriologists so seldom examine suspicious waters or the presence of typhoid bacilli since experience has shown that when such waters are examined the long period that
0215 has elapsed since infection has permitted the dying out of
bacilli. In one of the cases that I have presented, namely hat by Kubler and Neufeld the evidence indicated that the typhoid bacilli had been introduced in pure culture, so to speak, n the well water in which they were found, namely in the rine of typhoid fever patients containing only typhoid fever erms. The absence of competing fecal bacteria might account or the relative long life of typhoid bacilli in the well water

under these conditions. It is apparently only in such accidental cases that typhoid bacilli survive long enough in water to be found at so late a date as that at which the bacteriological examination is usually undertaken. If one knew just when a given water supply were to be heavily infected with typhoid bacilli and if a proper investigation of such a supply should be undertaken the positive findings would be more numerous than they can possibly be at present, where the stable is not locked until after the horse is stolen.

Q. In water that is infected the typhoid fever germs at the ratio of one germ to each pint of water, could those germs be easily detected by a bacterial analysis?

A. They could not.

Q. If a thousand samples of that water were examined, each sample representing one cubic centimeter, what, in 10216 your opinion, would be the probability of it being detected?

A. It is not likely that it would be.

Q. What in your opinion as a bacteriologists in the examination of water supplies is the necessary distributive number of typhoid bacteria as to guarantee positive typhoid results in the analyses?

A. Assuming in your question that proper methods were used by a bacteriologist, with proper and special experience in this kind of an investigation, and assuming that 10 cc. of water were examined, and that typhoid bacilli were distributed in such a way that there was one in each cc., I think that with water of ordinary bacterial content typhoid bacilli should be found in one-half of the samples. It might be found in them all, and would if a sufficiently detailed examination were made.

Q. And unless the greatest of care would be used it might not be found in any?

A. My answer assumed that the examination was made properly and by a skilled and an experienced observer.

Q. At the rate of one bacilli for each cc. of water how many would that be per pint, Professor?

A. About 500.

10217 Q. Now in making these determinations where the typhoid germ is distributed throughout the water at the rate of one germ to each cc. of water the ability to find these specific germs in that water by the analysis would depend largely upon the presence of other bacteria would it not?

A. Very largely.

Q. In what way would the presence of these other bacteria affect the finding of the typhoid?

A. Their presence would increase the number of plates that must be made in order to bring about a suitable separation of the colonies developing thereon, and would increase the labor in this way.

Q. Would their presence in any way bring about an overgrowth of colonies or by reason of their great number submerge the typhoid colony on the plate?

A. Special media are used for this kind of investigation and these may suppress a very large percentage of the ordinary sewage bacteria, while allowing the typhoid bacillus and some nearly related forms to grow. Where these plates are made properly the colonies are absolutely distinct and separate and there is only a remote chance of the obscuration of the typhoid colony by some other colony.

10218 Q. Is it not a difficult matter, Professor, to distinguish at all times the difference between colon and the typhoid?

A. Not when these special media are used. It is on the contrary very simple. The mere color of the colony, according to the media used, red or blue, enables one to effect an instant and complete differentiation with the naked eye.

Q. Does this special media about which you speak have a tendency to retard the colon or does it develop with the same precision as the typhoid?

A. These media permit the development of the colon colonies, but differentiate their colonies from those of the typhoid bacillus.

Q. Professor, in the analysis of water that is known to have been infected with typhoid germs, and afterwards analyzed, was there any information preserved with reference to the extent of the coli present in any of the cases which you have referred to in your testimony?

A. Yes, I have in several cases the record of the number of colon bacilli. I can get those if you want them.

Q. No, I don't care anything about that. In your opinion does the extent of the coli throw any light upon the extent of the infection so far as the particular cases referred to in the last preceding question are concerned?

A. In reply to that I can only state that at the time I
10219 examined the Chicago water in the autumn of 1902,
shortly after the great epidemic of that year, the number of colon bacilli in the water was higher than I had found it at any previous time. I had made no systematic observation of the Chicago water for any long period but during the ten preceding years I had at occasional intervals and on some occasions for periods of several months made examinations of such water to determine the presence of coli bacilli and at no time had there been as much typhoid fever in the city as in the summer of 1902. At no time also had I found the colon bacilli so abundant in the water as in the fall of 1902, just after the especially severe outbreak of that year.

Q. Do you know whether the water at Butler was being examined by bacteriologists when you were there?

A. It was.

Q. Do you know whether there was an increase in the coli as shown by those examinations over what was shown prior to the epidemic?

A. So far as I know, no examinations had been made prior to the epidemic.

Q. Going back now to the subject of infection would you consider 500 typhoid germs per pint of water and that distribution maintained throughout the water supply as being highly infected?

A. I have not given very careful consideration to establishing a limit for what constitutes a highly infectious
10220 water. I should think that water with 500 bacilli per pint
was certainly much more dangerous than one averaging one typhoid bacillus per pint and that the danger from drinking such water would be much greater in the former case than in the latter.

Q. Is it not a fact that no sanitarian has given the permissible extent of infection much study, but that all efforts so far as sanitarians are concerned has been to the elimination of infection and to a study of its possible presence?

A. I think that is true.

Adjourned until 2:00 P. M., February 12, 1904.

2:00 P. M., Friday, February 12, 1904.

10221 Continuation pursuant to adjournment.

Present, the Commissioner and same counsel representing the respective parties.

PROF. EDWIN O. JORDAN

resumed the stand for further cross examination by Mr. Jeffries, and testified as follows:

Q. Professor, there is nothing in sanitary science that undertakes to fix a standard of permissible infection is there?

A. I know of no standard of permissible infection.

Q. What are the elements that enter into the determination of the sanitary condition of a given water supply by an expert sanitarian?
